

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

ANATOMY

DESCRIPTIVE AND APPLIED

BY

HENRY GRAY, F.R.S.

FELLOW OF THE ROYAL COLLEGE OF SURGEONS; LECTURER ON ANATOMY AT ST. GEORGE'S
HOSPITAL MEDICAL SCHOOL, LONDON

A NEW AMERICAN

FROM THE EIGHTEENTH ENGLISH EDITION

THOROUGHLY REVISED AND RE-EDITED

WITH THE BASLE ANATOMICAL NOMENCLATURE
IN ENGLISH

BY

ROBERT HOWDEN, M.A., M.B., C.M.

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF DURHAM, ENGLAND

Illustrated with 1126 Engravings

LEA & FEBIGER
PHILADELPHIA AND NEW YORK
1913

THE FIRST EDITION OF THIS WORK

WAS DEDICATED TO

SIR BENJAMIN COLLINS BRODIE, BART., F.R.S., D.C.L.

IN ADMIRATION OF

HIS GREAT TALENTS

AND IN REMEMBRANCE OF

MANY ACTS OF KINDNESS SHOWN TO THE ORIGINAL

AUTHOR OF THE BOOK

FROM AN

EARLY PERIOD OF HIS PROFESSIONAL CAREER

PREFACE.

THE outstanding modification in the text of this edition is the use of the Basle nomenclature. Except in one or two instances, this nomenclature has been adopted in its entirety; in most cases English translations of the Latin terms are employed, but in those cases where the Latin terms have become fixed by routine usage it has been deemed desirable to retain them. Where the Basle nomenclature differs materially from the older terminology, the latter has been added in brackets, and for further convenience a glossary is appended showing (a) the terms adopted in the text, (b) the Basle, and (c) the old terminology.

The paragraphs on Surface Anatomy, which in previous editions were appended separately to the descriptions of the various structures, have been collected and recast into a special chapter—an arrangement which admits of more easy reference.

The section on Histology has been shortened. The elementary tissues are described in it, but the complex tissues are considered along with the organs to which they are specially related. The whole text has been thoroughly revised and, where necessary, rewritten.

About two hundred new engravings have been added; some of them replace older figures, but many are additional, and the majority are drawn from original preparations.

The notes on Applied Anatomy have been revised by A. J. JEX-BLAKE, M.A., M.B., B.Ch., F.R.C.P., Assistant Physician to St. George's Hospital, London, and W. FEDDE FEDDEN, M.S., F.R.C.S., Assistant Surgeon and Lecturer on Surgical Anatomy in St. George's Hospital, London, England.

I am deeply indebted to DR. J. ACKWORTH MENZIES, Lecturer on Physiology, and to DRs. J. DUNLOP LICKLEY and J. C. BOILEAU GRANT, Demonstrators of Anatomy in this University. Dr. Menzies revised the histological part of the book, and furnished a number of microscopic preparations for drawings. Dr. Lickley helped to revise the text, arranged the chapter on Surface Anatomy and Surface Markings, and passed the book through the press. Dr. Grant prepared the dissections for the new illustrations and assisted in the revision of the text.

I am also indebted to that skilled anatomical artist Mr. Sydney T. Sewell, who made the drawings for the new illustrations and who spared no pains to produce clear and accurate figures.

ROBERT HOWDEN.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE,
NEWCASTLE-UPON-TYNE, 1913.

PUBLISHERS' NOTE.

BOOKS, like men, have characters that can be analyzed to a certain point, but beyond or below lies a quality, subtle as life, and incapable of analysis or imitation, which is called personality. The greater the author, and the more intense his mental action in creating his book, the more it partakes of this element. This principle, so clear as to be almost axiomatic, is illustrated to the fullest extent in the work in hand. Henry Gray combined two faculties, either one sufficient to make his name famous. He was a great anatomist and a great teacher. He possessed a thorough knowledge of anatomy and an equal insight into the best methods of imparting it to other minds. His text was unequalled in clearness, and he united with it a series of incomparable illustrations. He devised the method of engraving the names of the parts directly upon them, thereby exhibiting at a glance not only their nomenclature, but also their position, extent, and relations. His work, still unique in this respect, was also the first to employ colors. Summing all, it is hardly to be wondered at that students and teachers alike find their labors reduced and the permanence of knowledge increased by the use of this book.

On its original appearance, over half a century ago, *Gray* immediately took the leading place, and it has not only maintained its position in its own subject, but has also become the best-known work in all medical literature. It is incomparably the greatest text-book in medicine, measured by the number of students who use it, and it is unique also in being the one work which is certain to be carried from college to afford guidance in the basic questions underlying practice.

The consequent demand is evidenced in the number of editions, which collectively represent the labors of many of the leading anatomists since the early death of its talented author. In this new revision every line has been carefully considered, any possible obscurity has been clarified, the latest accessions to anatomical knowledge have been introduced, and much has been rewritten. Care has been exercised to make the text a homogeneous, sequential, and complete presentation of the subject, meeting every need of the student, physician, or surgeon.

As directions are given for dissecting, this volume will serve every requirement of the student throughout his course. The Basle Anatomical Nomenclature in English has been used in the text and on the engravings, this being preferable to the Latin form in the judgment of such eminent anatomists as Professor Howden and Professor Mall. A Glossary exhibiting the three accepted nomenclatures in parallel columns will be found a great convenience. The Table of Contents is so arranged as to give a complete conspectus of anatomy, a feature of obvious value. The whole book is thoroughly organized in its headings and the sequence of subjects, so that the student receives his knowledge of the parts in their anatomical dependence.

As a teaching instrument the new *Gray's Anatomy* embodies all that careful thought and unstinted expenditure can combine in a text-book.

CONTENTS.

HISTOLOGY.

<i>The Animal Cell.</i>		Cartilage	47
Protoplasm	33	Hyaline Cartilage	47
Nucleus	34	White Fibrocartilage	49
Reproduction of Cells	34	Yellow or Elastic Fibrocartilage	50
Prophase	35	Bone	50
Metaphase	36	Structure and Physical Properties	50
Anaphase	36	Periosteum	51
Telophase	36	Marrow	51
		Vessels and Nerves of Bone	52
		Ossification	56
		Applied Anatomy	59
<i>Epithelium.</i>			
Simple Epithelium	37	<i>The Circulating Fluids.</i>	
Simple Squamous or Pavement Epithelium	37	Blood	61
Columnar or Cylindrical Epithelium	37	General Composition of the Blood	61
Glandular Epithelium	37	Lymph	64
Ciliated Epithelium	37		
Stratified Epithelium	39	<i>The Muscular Tissue.</i>	
Transitional Epithelium	40	Striped or Voluntary Muscle	64
		Vessels and Nerves of Striped Muscle	67
<i>Connective Tissue.</i>		Unstriated Plain or Involuntary Muscle	67
The Connective Tissues Proper	40	Cardiac Muscular Tissue	68
Areolar Tissue	40	Development of Muscle Fibres	69
Adipose Tissue	42		
White Fibrous Tissue	43	<i>The Nervous Tissue.</i>	
Yellow Elastic Tissue	44	Neuroglia	70
Mucous Tissue	44	Nerve Cells	70
Retiform or Reticular Tissue	44	Nerve Fibres	73
Basement Membranes	45	Wallerian Degeneration	76
Vessels and Nerves of Connective Tissue	46	Non-medullated Fibres	76
Pigment	46		
Applied Anatomy	46		
Development of Connective Tissue	47		

EMBRYOLOGY.

<i>The Ovum.</i>		Separation of the Embryo	92
Yolk	78	<i>The Yolk-sac</i>	
Germinal Vesicle	78		93
Coverings of the Ovum	79	<i>Development of the Fetal Membranes and Placenta.</i>	
Maturation of the Ovum	79	The Allantois	93
		The Amnion	94
<i>The Spermatozoön</i>		The Umbilical Cord and Body-stalk	96
	80	Implantation or Imbedding of the Ovum	97
<i>Fertilization of the Ovum</i>		The Decidua	98
	82	The Chorion	99
<i>Segmentation of the Fertilized Ovum.</i>		The Placenta	100
The Primitive Streak; Formation of the		Fetal Portion	100

INTRODUCTION.

THE term *human anatomy* comprises a consideration of the various structures which make up the human organism. In a restricted sense it deals merely with the parts which form the fully developed individual and which can be rendered evident to the naked eye by various methods of dissection. Regarded from such a standpoint it may be studied by two methods: (1) the various structures may be separately considered—**systematic anatomy**; or (2) the organs and tissues may be studied in relation to one another—**topographical** or **regional anatomy**.

It is, however, of much advantage to add to the facts ascertained by naked-eye dissection those obtained by the use of the microscope. This introduces two fields of investigation, viz., the study of the minute structure of the various component parts of the body—**histology**—and the study of the human organism in its immature condition, *i. e.*, the various stages of its intrauterine development from the fertilized ovum up to the period when it assumes an independent existence—**embryology**. Owing to the difficulty of obtaining material illustrating all the stages of this early development, gaps must be filled up by observations on the development of lower forms—**comparative embryology**, or by a consideration of adult forms in the line of human ancestry—**comparative anatomy**. The direct application of the facts of human anatomy to the various pathological conditions which may occur constitutes the subject of **applied anatomy**. Finally, the appreciation of structures on the immediately underlying surface of the body is frequently made the subject of special study—**surface anatomy**.

SYSTEMATIC ANATOMY.—The various systems of which the human body is composed are grouped under the following headings:

1. **Osteology**—the bony system or skeleton.
2. **Syndesmology**—the articulations or joints.
3. **Myology**—the muscles. In the description of the muscles it is convenient to include that of the fasciæ which are so intimately connected with them.
4. **Angiology**—the vascular system, comprising the heart, bloodvessels, lymphatic vessels, and lymph glands.
5. **Neurology**—the nervous system. The organs of sense may be included in this system.
6. **Splanchnology**—the visceral system. Topographically the viscera form two groups, viz., the thoracic viscera and the abdominopelvic viscera. The heart, a thoracic viscus, is best considered with the vascular system. The rest of the viscera may be grouped according to their functions: (a) the **respiratory apparatus**; (b) the **digestive apparatus**; (c) the **urogenital apparatus**. Strictly speaking, the third subgroup should include only such components of the urogenital apparatus as are included within the abdominopelvic cavity, but it

is convenient to study under this heading certain parts which lie in relation to the surface of the body, *e. g.*, the testes and the external organs of generation.

For descriptive purposes the body is supposed to be in the erect posture, with the arms hanging by the sides and the palms of the hands directed forward. The *median plane* is a vertical antero-posterior plane, passing through the centre of the trunk. This plane will pass approximately through the sagittal suture of the skull, and hence any plane parallel to it is termed a *sagittal plane*. A vertical plane at right angles to the median plane passes, roughly speaking, through the central part of the coronal suture or through a line parallel to it; such a plane is known as a *frontal plane* or sometimes as a *coronal plane*. A plane at right angles to both the median and frontal planes is termed a *transverse plane*.

The terms *anterior* or *ventral*, and *posterior* or *dorsal*, are employed to indicate the relation of parts to the front or back of the body or limbs, and the terms *superior* or *cephalic*, and *inferior* or *caudal*, to indicate the relative levels of different structures; structures nearer to or farther from the median plane are referred to as *medial* or *lateral* respectively.

The terms *superficial* and *deep* are strictly confined to descriptions of the relative depth from the surface of the various structures; *external* and *internal* are reserved almost entirely for describing the walls of cavities or of hollow viscera. In the case of the limbs the words *proximal* and *distal* refer to the relative distance from the attached end of the limb.

DESCRIPTIVE AND APPLIED ANATOMY.

HISTOLOGY.

THE ANIMAL CELL (Fig. 1).

ALL the tissues and organs of the body originate from a microscopic structure (the **fertilized ovum**), which consists of a soft jelly-like material enclosed in a membrane and containing a vesicle or small spherical body inside which are one or more denser spots. This may be regarded as a complete cell. All the solid tissues consist largely of cells essentially similar to it in nature but differing in external form.

FIG. 1.—Diagram of a cell. (Modified from Wilson.)

In the higher organisms a cell may be defined as “a nucleated mass of protoplasm of microscopic size.” Its two essentials, therefore, are: a soft jelly-like material, similar to that found in the ovum, and usually styled **protoplasm**, and a small spherical body imbedded in it, and termed a **nucleus**. Some of the unicellular protozoa contain no nuclei but granular particles which, like true nuclei, stain with basic dyes. The other constituents of the ovum, viz., its limiting membrane and the denser spot contained in the nucleus, called the **nucleolus**, are not essential to the type cell, and in fact many cells exist without them.

Protoplasm (*cytoplasm*) is a material probably of variable constitution during life, but yielding on its disintegration bodies chiefly of proteid nature. Lecithin and cholesterin are constantly found in it, as well as inorganic salts, chief among which are the phosphates and chlorides of potassium, sodium, and calcium. It is of a semifluid viscid consistence, and in the living condition appears to be homo-

geneous and structureless. When, however, cells have been "fixed" by reagents a fibrillar or granular appearance can often be made out under a high power of the microscope. The fibrils are usually arranged in a network or reticulum, to which the term **spongioplasm** is applied, the clear substance in the meshes being termed **hyaloplasm**. A granular appearance is often caused by the knots of the network; but, in addition to these, protoplasm frequently contains true granules, some of which are proteid in nature and probably essential constituents; others are fat, glycogen, or pigment granules, and are regarded as adventitious material taken in from without, and hence are styled cell-inclusions or **paraplastm**. The size and shape of the meshes of the spongioplasm vary in different cells and in different parts of the same cell. The relative amounts of spongioplasm and hyaloplasm also vary in different cells, the latter preponderating in the young cell and the former increasing at the expense of the hyaloplasm as the cell grows. The peripheral layer of a cell is in all cases modified, either by the formation of a definite **cell membrane** as in the ovum, or more frequently in the case of animal cells, by a transformation, probably chemical in nature, which is only recognizable by the fact that the surface of the cell behaves as a semipermeable membrane.

Nucleus.—The nucleus is a minute body, imbedded in the protoplasm, and usually of a spherical or oval form, its size having little relation to that of the cell. It is surrounded by a well-defined wall, the **nuclear membrane**; this encloses the **nuclear substance** (*nuclear matrix*), which is composed of a homogeneous material or **karyoplasm** containing a network or **karyomitome**. The former is probably of the same nature as the hyaloplasm of the cell, but the latter, which forms also the wall of the nucleus, differs from the spongioplasm of the cell substance. It consists of fibres or filaments arranged in a reticular manner. These filaments are composed of a homogeneous material known as **linin**, which stains with acid dyes and contains embedded in its substance particles which have a strong affinity for basic dyes. These basiphil granules have been named **chromatin** or **basichromatin** and owe their staining properties to the presence of nucleic acid.

Within the nuclear matrix are one or more highly refracting bodies, termed **nucleoli**, connected with the nuclear membrane by the nuclear filaments. They are regarded as being of two kinds. Some are mere local condensations ("net-knots") of the chromatin; these are irregular in shape and are termed **pseudo-nucleoli**; others are distinct bodies differing from the pseudo-nucleoli both in nature and chemical composition; they may be termed **true nucleoli**, and are usually found in resting cells. The true nucleoli are oxyphil, *i. e.*, they stain with acid dyes.

Most living cells contain, in addition to their protoplasm and nucleus, a small particle which usually lies near the nucleus and is termed the **centrosome**. In the middle of the centrosome is a minute body called the **centriole**, and surrounding this is a clear spherical mass known as the **centrosphere**. The protoplasm surrounding the centrosphere is frequently arranged in radiating fibrillar rows of granules, forming what is termed the **attraction sphere**.

Reproduction of Cells.—Reproduction of cells is effected either by **direct** or by **indirect division**. In reproduction by **direct division** the nucleus becomes constricted in its centre, assuming an hour-glass shape, and then divides into two. This is followed by a cleavage or division of the whole protoplasmic mass of the cell; and thus two daughter cells are formed, each containing a nucleus. These daughter cells are at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may take place rapidly. **Indirect division** or **karyokinesis** (*karyomitosis*) has been observed in all the tissues—generative cells, epithelial tissue, connective tissue, muscular tissue, and nerve tissue. It is possible that cell division may always take place by the indirect method, and that in those cases in which direct division has been described the intermediate stages may not have been seen, owing to the process occurring more rapidly than usual.

The process of indirect cell division is characterized by a series of complex changes in the nucleus, leading to its subdivision; this is followed by cleavage of the cell protoplasm. Starting with the nucleus in the quiescent or **resting stage**, these changes may be briefly grouped under the four following phases (Fig. 2).

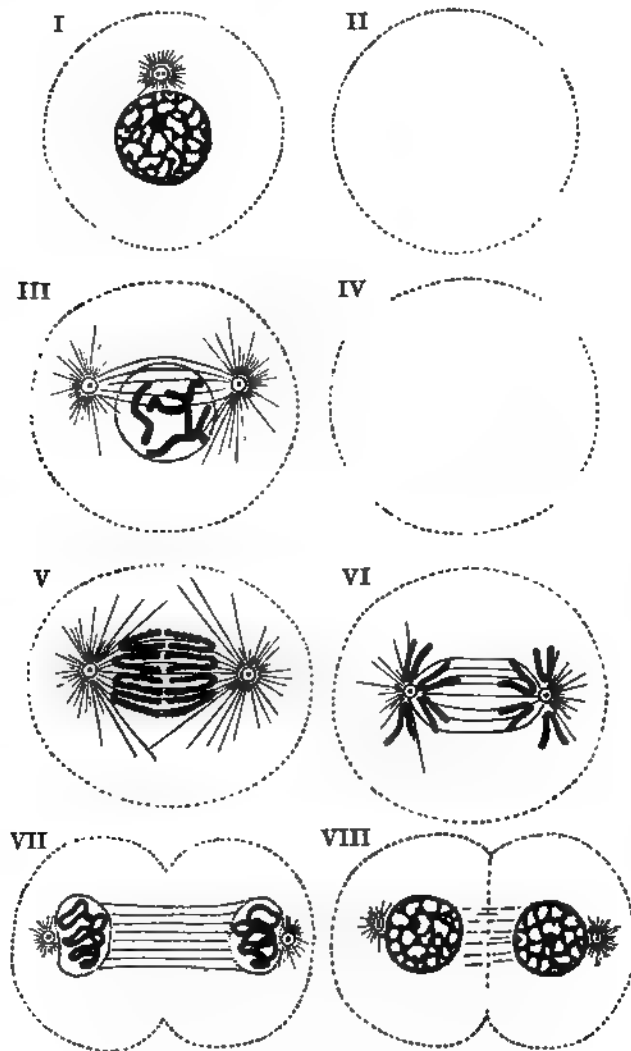

FIG. 2.—Diagram showing the changes which occur in the centrosomes and nucleus of a cell in the process of mitotic division. (Schäfer.) I to IV, prophase; V and VI, metaphase; VII and VIII, anaphase.

1. **Prophase.**—The nuclear network of chromatin filaments assumes the form of a twisted *skein* or *spirem*, while the nuclear membrane and nucleolus disappear. The convoluted skein of chromatin divides into a definite number of V-shaped segments or **chromosomes**. The number of chromosomes varies in different animals, but is constant for all the cells in an animal of any given species; in man the number is given by Flemming and Duesberg as twenty-four.¹ Coincidentally with or preceding these changes the centriole, which usually lies by the side of the nucleus, undergoes subdivision, and the two resulting centrioles, each surrounded by a centrosphere, are seen to be connected by a spindle of delicate achromatic fibres

¹ Dr. J. Duesberg, *Anat. Ans.*, Band xxviii, S. 475.

the **achromatic spindle**. The centrioles move away from each other—one toward either extremity of the nucleus—and the fibrils of the achromatic spindle are correspondingly lengthened. A line encircling the spindle midway between its extremities or **poles** is named the **equator**, and around this the V-shaped chromosomes arrange themselves in the form of a star, thus constituting the **mother star** or **monaster**.

2. **Metaphase**.—Each V-shaped chromosome now undergoes longitudinal cleavage into two equal parts or **daughter chromosomes**, the cleavage commencing at the apex of the V and extending along its divergent limbs. The daughter chromosomes, thus separated, travel in opposite directions along the fibrils of the achromatic spindle toward the centrioles, around which they group themselves, and thus two star-like figures are formed, one at either pole of the achromatic spindle. This constitutes the **diaster**.

3. **Anaphase**.—The daughter chromosomes now arrange themselves into a *skein* or *spirem*, and eventually form the network of chromatin which is characteristic of the resting nucleus. The nuclear membrane and nucleolus are also differentiated during this phase. The cell protoplasm begins to appear constricted around the equator of the achromatic spindle, where double rows of granules are also sometimes seen. The constriction deepens and the original cell gradually becomes divided.

4. **Telophase**.—In this stage the cell is completely divided into two new cells, each with its own nucleus and centrosome, which assume the ordinary positions occupied by such structures in the resting stage.

EPITHELIUM.

All the surfaces of the body—the external surface of the skin, the internal surfaces of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coats of the vessels, the acini and ducts of all secreting and excreting glands, the ventricles of the brain and the central canal of the medulla spinalis—are covered by one or more layers of simple cells, called **epithelium** or **epithelial cells**. These cells are also present in the terminal parts of the organs of special sense, and in some other structures, such as the hypophysis cerebri and the thyroid gland. They serve various purposes, in some cases forming a protective layer, in others acting as agents in secretion and excretion, and again in others being concerned in the elaboration of the organs of special sense. Thus, in the skin, the main purpose served by the epithelium (here called the **epidermis**) is that of protection. As the surface is worn away by the agency of friction new cells are supplied, and thus the true skin and the vessels and nerves which it contains are defended from damage. In the gastro-intestinal mucous membrane and its glands, the epithelial cells appear to be the principal agents in preparing the digestive secretions, and in selecting and modifying materials for absorption. In other situations (as the nose, fauces, and respiratory passages) an important office of the epithelial cells appears to be to maintain an equable temperature by the moisture with which they keep the surface always slightly lubricated. In the serous cavities they also keep the opposed layers moist, and thus facilitate their movements on each other. Finally, in all internal parts, they ensure a perfectly smooth surface.

Epithelium consists of one or more layers of cells usually supported on a basement membrane and united together by an interstitial cement substance which appears to be similar in chemical composition to the matrix or ground substance of the connective tissues. It is naturally grouped into two classes according as to whether there is a single layer of cells (**simple epithelium**), or more than one (**stratified epithelium** and **transitional epithelium**).

Simple Epithelium.—The different varieties of simple epithelium are squamous or pavement, columnar, glandular, and ciliated.

Simple Squamous or Pavement Epithelium (Fig. 3) is composed of flat, nucleated scales of different shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal; the flattening depends upon the thinness of the cell. The protoplasm of the cell presents a fine reticulum or honey-combed network, which gives to the cell the appearance of granulation. This kind of epithelium forms the lining of the air-sacs of the lungs. The so-called **endothelium**, which covers the serous membranes, and which lines the heart, bloodvessels, and lymphatics, is also of the pavement type, being composed of a single layer of flattened transparent squamous cells, joined edge to edge in such a manner as to form a membrane of cells.

FIG. 3.—Simple pavement epithelium.

FIG. 4.—Columnar epithelial cells of the rabbit's intestine. (Schäfer.) *str.*, striated border; *n.*, nucleus.

Columnar or Cylindrical Epithelium (Fig. 4) is formed of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, flattened from mutual pressure, and are set upright on the surface on which they are supported. Their protoplasm is always more or less reticulated, and fine longitudinal striæ may be seen in it; the nucleus of each is oval in shape and contains an intranuclear network. In the case of the intestinal villi, the outer free border of each of these cells is distinctly marked off from the rest of the protoplasm, and contains well-defined vertical striations. Columnar epithelium covers the mucous membrane and nearly the whole gastro-intestinal tract and its glands, the greater part of the male urethra, the ductus deferens, the prostate, the bulbo-urethral glands of Cowper, and the vestibular glands of Bartholin. In a modified form it also covers the ovary.

Goblet or chalice cells are modified columnar cells. The goblet cell appears to be formed by an alteration in shape of a columnar cell (ciliated or otherwise) consequent on the formation of granules, which consist of a substance called **mucigen**, in the interior of the cell. This distends the upper part of the cell, while the nucleus is pressed down toward its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane (Fig. 5), the cell then assuming the shape of an open cup or chalice.

Glandular Epithelium (Fig. 6) is composed of polyhedral, columnar, or cubical cells. As in other forms of epithelial cells, the protoplasm shows a fine reticulum, which gives to the cells the appearance of granulation. Granular cells are found in the terminal recesses of secreting glands, and the protoplasm of the cells usually contains the materials which the cells secrete.

Ciliated Epithelium (Fig. 7) generally inclines to the columnar shape. It is distinguished by the presence of minute processes, like hairs or eyelashes (*cilia*) standing up from the free surface. The cilia (Fig. 8) at their points of attachment

to the free border of the cell possess small nodular enlargements (**basal knobs of Engelmann**); within the cell they converge, and according to some authorities meet at or near the attraction sphere. If the cells be examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells be separated, they will often be seen to be moved about in the field by this ciliary action.

FIG. 5.—Goblet cells of frog. $\times 500$.

FIG. 6.—Isolated liver cells of rabbit. $\times 500$.

FIG. 7.—Ciliated epithelium from trachea of kitten. $\times 255$.

Basal knobs

FIG. 8.—Isolated ciliated cell (semidiagrammatic).

FIG. 9.—Stratified epithelium from the oesophagus.

The situations in which ciliated epithelium is found in the human body are: the respiratory tract from the nose downward to the smallest ramifications of the bronchial tubes, except the lower part of the pharynx and the surfaces of the vocal folds; the tympanic cavity and auditory tube; the uterine tube and the body of the uterus; the vasa efferentia, coni vasculosi and the first part of the ductus deferens; the ventricles of the brain and the central canal of the medulla spinalis.

Stratified Epithelium (Fig. 9).—Stratified epithelium consists of several layers of cells varying greatly in shape. The cells of the deepest layer are for the most part columnar, and are placed vertically on the basement membrane; above these are several layers of polyhedral cells, which as they approach the surface become more and more compressed, until the superficial ones are found to consist of flattened scales (Fig. 10), the margins of which overlap one another so as to present an imbricated appearance. The protoplasm of the superficial cells is completely converted into a horny substance termed **keratin**. An intermediate body, **eleidin**, is often present in the deeper layers of this superficial portion; it exists in the form of coarse granules, and is especially well seen in the stratum granulosum of the epidermis (Fig. 11). The most superficial layers lose their nuclei, die, and are thrown or worn off.

FIG. 10.—Epithelial cells from the oral cavity of man. $\times 330$. a, large; b, middle sized; c, the same with two nuclei

FIG. 11.—Portion of epidermis from a section of the skin of the finger. (Ranvier.)

The cells of the deeper layers of stratified squamous epithelium are called **prickle cells**; they possess short, fine fibrils, which pass from their margins to those of neighboring cells, serving to connect them together. They are not closely joined together by cement-substance, but are separated from each other by intercellular channels, across which the fibrils may be seen bridging. When a cell is isolated, it appears to be covered over with a number of short spines, in consequence of the fibrils being broken through. These cells were first described by Max Schultze and Virchow, and it was believed by them that the cells were dovetailed together. Martyn subsequently showed that this was not the case and that the prickles were attached to each other by their apices; and Delépine believes the prickles to be parts of fibrils forming internuclear bundles between the nuclei of the cells of an epithelium in a state of active growth.

Stratified epithelium is found in the skin, in the conjunctiva, in the mucous membrane of the nose, excepting the olfactory portion, and in the mucous membrane of the mouth, lower part of the pharynx, and oesophagus.

Transitional Epithelium.—Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are large and flattened, with depressions on their under surfaces, to fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement membrane. Between the tapering points of the cells of the second layer is a third variety of cells of smaller size than those of the other two layers (Fig. 12).

FIG. 12.—Transitional epithelium.

CONNECTIVE TISSUES.

The term **connective tissue** includes a number of tissues which support and connect the other tissues of the body; they are composed of cells separated from one another by an intercellular material. The connective tissues may differ considerably from each other in appearance, but they present many points of relationship, and are, moreover, developed from the same layer of the embryo, the mesoderm. They are divided into three great groups: (1) the **connective tissues proper**, (2) **cartilage**, and (3) **bone**. The circulating fluids, although functionally and probably developmentally different from the others, are regarded by some histologists as a form of connective tissue, and are dealt with therefore in this section.

The Connective Tissues Proper.—Several varieties of connective tissue are recognized: (1) **Areolar tissue**. (2) **White fibrous tissue**. (3) **Yellow elastic tissue**. (4) **Mucous tissue**. (5) **Retiform tissue**. They are all composed of a homogeneous matrix, in which are imbedded cells and fibres—the latter of two kinds, white, and yellow or elastic. The distinction between the different varieties depends upon the relative preponderance of one or other kind of fibre, of cells, or of matrix.

Areolar Tissue.—This is so called because its meshes can be easily distended with air or fluid and thus separated into areolæ or spaces, which open freely into each other. Such spaces, however, do not exist in the natural condition of the body, the whole tissue forming one unbroken membrane composed of a number of interlacing fibres. The chief use of areolar tissue is to bind parts together, while by the laxity of its fibres, and the permeability of its areolæ, it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids. It is quite the most extensively distributed of all the tissues. It is found beneath the skin in a continuous layer all over the body, connecting it to the subjacent parts. In the same way it is situated beneath the mucous and serous membranes. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. In addition to this it is present in the interior of organs, binding together the various lobes and lobules of the compound glands, the various coats of the hollow viscera, the fibres of muscles, etc., and thus forms the most important connecting medium of the various structures or organs of which the body is made up. In many parts the areolæ or inter-spaces of areolar tissue are occupied by fat cells, constituting **adipose tissue**, which will presently be described.

Areolar tissue presents to the naked eye an appearance somewhat like spun silk. When stretched out, it is seen to consist of delicate soft elastic threads

interlacing with each other in every direction, and forming a network of extreme delicacy. When examined under the microscope (Fig. 13) it is found to be composed of **white fibres** and **yellow elastic fibres** intercrossing in all directions, and united together by a homogeneous cement or ground substance, the **matrix**, showing cell-spaces wherein lie the **connective tissue corpuscles**; these contain the protoplasm out of which the whole is developed and regenerated.

↓
Lamellar cell

FIG. 13.—Subcutaneous tissue from a young rabbit. Highly magnified. (Schäfer)

The **white fibres** are arranged in wavy bands or bundles of minute transparent homogeneous filaments or fibrillæ. The bundles have a tendency to split up longitudinally or send off slips to join neighboring bundles, and receive others in return, but the individual fibres are unbranched, and never join other fibres. The **yellow elastic fibres** have well-defined outlines and are considerably larger in size than the white fibrillæ, but vary much, being from 1 to 6 μ in diameter. They form bold and wide curves, branch, and freely anastomose with each other; they are homogeneous in appearance, and tend to curl up, especially at their broken ends.

The cells of areolar tissue are of four principal kinds: (1) Flattened **lamellar cells**, which may be either branched or unbranched. The branched lamellar cells are composed of clear cytoplasm, and contain oval nuclei; the processes of these cells may unite so as to form an open network, as in the cornea. The unbranched cells are joined edge to edge like the cells of an epithelium; the "tendon cells," presently to be described, are examples of this variety. (2) **Clasmatocytes**, large irregular cells characterized by the presence of granules or vacuoles in their protoplasm, and containing oval nuclei. (3) **Granule cells** (*Mastzellen*), which are ovoid or spheroidal in shape. They are formed of a soft protoplasm, containing granules which are basophil in character. (4) **Plasma cells** of Waldeyer, usually spheroidal and distinguished by containing a vacuolated protoplasm. The vacuoles are filled

with fluid, and the protoplasm between the spaces is clear, with occasionally a few scattered basophil granules.

In addition to these four typical forms of connective-tissue corpuscles, areolar tissue may be seen to possess **wandering cells**, *i. e.*, leucocytes which have emigrated from the neighboring vessels; in some instances, as in the choroid coat of the eye, cells filled with granules of pigment (**pigment cells**) are found.

The cells lie in spaces in the ground substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light. This will color the ground substance and leave the cell-spaces unstained.

Adipose Tissue.—In almost all parts of the body the ordinary areolar tissue contains a variable quantity of fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, of the penis and scrotum, of the labia minora; within the cavity of the cranium; and in the lungs, except near their roots. The distribution of adipose tissue is not uniform; in some parts it is in great abundance, as in the subcutaneous tissue, especially of the abdomen, around the kidneys, and in some other situations. Lastly, fat enters largely into the formation of the marrow of bones.

FIG. 14.—Adipose tissue. Highly magnified. *a*, star-like appearance, from crystallization of fatty acids.

Adipose tissue consists of small vesicles, **fat cells**, lodged in the meshes of areolar tissue. Fat cells (Fig. 14) vary in size, but are of about the average diameter of 50μ ; each consists of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less polygonal outline. A nucleus is always present under the cell membrane and can be easily demonstrated by staining with hematoxylin; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognizable. The fat cells are contained in clusters in the areolæ of fine connective tissue, and are held together mainly by the network of capillary blood-vessels which is distributed to them.

Chemically the oily material in the cells is composed of the fats, olein, palmitin, and stearin, which are glycerin compounds with fatty acids. Sometimes fat crystals form in the cells after death (Fig. 14, *a*). By boiling the tissue in ether or strong alcohol the fat may be extracted from the vesicles, leaving them empty and shrunken.

Fat may be first detected in the human embryo about the fourteenth week. The fat cells are formed by the transformation of connective-tissue corpuscles.

Small droplets of oil are formed in the protoplasm, and these coalesce to produce a larger drop, which increases until it distends the corpuscles, the remaining protoplasm and the nucleus being displaced toward the periphery of the cell (Fig. 15).

FIG. 15.—Development of fat. (Klein and Noble Smith.) a, minute artery; v, minute vein; c, capillary bloodvessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa; the ground substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

FIG. 16.—White fibres of areolar tissue. $\times 400$. (Sharpey.)

FIG. 17.—Tendon of mouse's tail, stained with logwood, showing chains of cells between the tendon bundles. (From Quain's "Anatomy." E. A. Schäfer.)

FIG. 18.—Transverse section of tendon of rat. $\times 120$.

White Fibrous Tissue (Fig. 16) is a true connecting structure, and serves three purposes in the animal economy. In the form of ligaments it binds bones together; in the form of tendons it connects muscles to bones or other structures; and it constitutes investing or protecting structures to various organs in the form of membranes. Examples of such membranes are to be found in the muscular fasciæ or sheaths, the periosteum, and the perichondrium; the investments of the various glands (such as the tunica albuginea testis, the capsule of the kidney, etc.); the investing sheaths of the nerves (*epineurium*), and of various organs, as the penis and the eye. In white fibrous tissue, as its name implies, the white fibres predomi-

nate; the matrix is apparent only as a cement-substance, the yellow elastic fibres are comparatively few, while the tissue cells are arranged in a special manner. It presents to the naked eye the appearance of silvery white glistening fibres, covered over with a quantity of loose flocculent tissue which binds the fibres together and carries the bloodvessels. It is not possessed of any elasticity, and only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence, a bone with which it is connected may fracture before the fibrous tissue gives way. In ligaments and tendons the bundles of fibres run parallel with each other; in membranes they intersect one another. The cells found in white fibrous tissue are often called **tendon cells**. They are situated on the surfaces of groups of bundles and are quadrangular in shape, arranged in rows, in single file, each cell being separated from its neighbors by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (Fig. 17). The tendon cells have wing-like processes which pass between the bundles of fibres, giving a stellate appearance in transverse section (Fig. 18). Upon the addition of acetic acid white fibrous tissue swells up into a glassy looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin, the white fibres being composed of the albuminoid **collagen**, which is often regarded as the anhydride of gelatin.

FIG. 19.—Elastic fibres. $\times 200$.
(Sharpey.)

Yellow Elastic Tissue.—In certain parts of the body a tissue is found which when viewed in mass is of a yellowish color, and is possessed of great elasticity, so that it is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*; it may be regarded as a connective tissue in which the yellow elastic fibres have developed to the practical exclusion of the other elements. It is found in the ligamenta flava, in the vocal folds, in the mucous membrane of the trachea and bronchi, in the coats of the bloodvessels, especially the larger arteries, and to a very considerable extent in the hyothyroid, cricothyroid, and stylohyoid ligaments. It is also found in the ligamentum nuchae of the lower animals (Fig. 19). In some parts where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding to the intervening spaces. This is to be found in the inner coat of the arteries, and to it the name of **fenestrated membrane** has been given by Henle. The yellow elastic fibres remain unaltered by acetic acid; chemically they are composed of the albuminoid body **elastin**.

Mucous Tissue.—Mucous tissue exists chiefly in the "jelly of Wharton," which forms the bulk of the umbilical cord, but is also found in other situations in the fetus, chiefly as a stage in the development of connective tissue. It consists of a matrix, largely made up of mucin, in which are nucleated cells with branching and anastomosing processes (Fig. 20). Few fibres are seen in typical mucous tissue, although at birth the umbilical cord shows a considerable development of fibres. In the adult the vitreous humor of the eye is a persistent form of mucous tissue, in which there are no fibres, and from which the cells have disappeared, leaving only the mucinous ground substance.

Retiform or Reticular Tissue (Fig. 21) is found extensively in many parts of the body, constituting the framework of some organs and entering into the construction of many mucous membranes. It is a variety of connective tissue, in which

the intercellular or ground substance has, in great measure, disappeared, and is replaced by fluid. It is apparently composed almost entirely of extremely fine bundles of white fibrous tissue, forming an intricate network, and chemically it yields gelatin. The fibres are covered and concealed in places by flattened branched connective tissue cells. In many situations the interstices of the network are filled with rounded lymph-corpuscles, and the tissue is then termed **lymphoid** or **adenoid tissue**.

FIG. 20.—Mucous tissue from the umbilical cord of the human fetus of four months.

FIG. 21 —Retiform tissue, from a lymph gland.

Basement Membranes, formerly described as homogeneous membranes, are in most cases really a form of connective tissue. They constitute the supporting membrane, or *membrana propria*, on which is placed the epithelium of mucous membranes or secreting glands, and they are also found in other situations. By

means of staining with nitrate of silver they may be shown to consist usually of flattened cells in close apposition, and joined together by their edges, thus forming an example of an epithelioid arrangement of connective tissue cells. In some situations the cells, instead of adhering by their edges, give off branching processes which join with similar processes of other cells, and so form a network rather than a continuous membrane. Some basement membranes are composed of elastic tissue, as in the cornea, others are merely condensed matrix.

Vessels and Nerves of Connective Tissue.—The *bloodvessels* of connective tissue are very few—that is to say, there are few actually destined for the tissue itself, although many vessels carrying blood to other structures may permeate one of its forms, the areolar tissue. In white fibrous tissue the bloodvessels usually run parallel to the longitudinal bundles and between them, sending transverse communicating branches across; in some forms, as in the periosteum and dura mater they are fairly numerous. In yellow elastic tissue, the bloodvessels also run between the fibres, and do not penetrate them. *Lymphatic vessels* are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves. *Nerves* are to be found in the white fibrous tissue, where they end in a special manner; but it is doubtful whether any nerves end in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Pigment.—In various parts of the body pigment is found; most frequently in epithelial cells and in the cells of connective tissue. Pigmented **epithelial cells** are found in the external layer of the retina, on the posterior surface of the iris, in the olfactory region of the nose, and in the membranous labyrinth of the ear. Pigment is likewise found in the cells of the deeper layers of the cuticle and in the hairs; in the skin of the colored races it is abundantly present, but in the white races it is well-marked only in the areolæ around the nipples and in irregular colored patches.

In the **connective tissue cells** pigment is frequently met with in the lower vertebrates. In man it is found in the choroid coat of the eye (Fig. 22), and in the iris of all but the light blue eyes and the albino. It is also occasionally met with in the cells of retiform tissue and in the pia mater of the upper part of the medulla spinalis. The cells are characterized by their large size and by branched processes, which are also filled with granules. In the retina the pro-

FIG. 22.—Pigment cells from the choroid coat of the eyeball.

cesses of the cells can be withdrawn or protruded under the influence of light in order to protect the delicate rods and cones. The pigment (**melanin**) consists of dark brown or black granules of very small size closely packed together within the cells, but not invading the nucleus. Occasionally the pigment is yellow, and when occurring in the cells of the cuticle constitutes "freckles." In the retina another variety of pigment occurs, known as **rhodopsin** or **visual purple**, which is bleached on exposure to light.

Applied Anatomy.—Abnormal pigmentation of the skin may be congenital, when it often takes the form of dark brown or black nevi (*moles*), scattered over a greater or smaller area of the body. It may also result from the prolonged consumption of various drugs, particularly of salts of silver or arsenic, being most marked wherever the skin is exposed to the action of light.

Progressive darkening or bronzing of the skin is also highly suggestive of Addison's disease, which commonly follows destruction or tuberculosis of the suprarenal glands; it is then most obvious in regions where the skin is normally pigmented or is subjected to pressure or irritation from the clothes. Pigmentation is also associated with certain disorders of the skin, of the female genitalia, and of the thyroid gland, and with the later stages of wasting diseases such as cancer and phthisis. It does not yield to any medical treatment as a rule.

Development of Connective Tissue.—Connective tissue is developed from cells of the mesoderm. These cells multiply and form a syncytium containing many nuclei. Later the protoplasm increases rapidly in amount, and in the vicinity of each nucleus is differentiated into two parts: (1) a portion surrounding the nucleus and forming ultimately the cytoplasm of the connective tissue cell; (2) an outlying portion in which fibrillation takes place. Both the white and the yellow elastic fibres are laid down in the same manner.

Cartilage.—Cartilage is a non-vascular structure which is found in various parts of the body—in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, such as the trachea and bronchi, nose, and ears, which require to be kept permanently open. In the fetus, at an early period, the greater part of the skeleton is cartilaginous; as this cartilage is afterward replaced by bone, it is called **temporary**, in contradistinction to that which remains unossified during the whole of life, and is called **permanent**.

Cartilage is divided, according to its minute structure, into **hyaline cartilage**, **white fibrocartilage**, and **yellow or elastic fibrocartilage**. Besides these varieties met with in the adult human subject, there is a variety called **cellular cartilage**, which consists entirely, or almost entirely, of cells, separated from each other by their capsules only, which in this kind of cartilage are extremely well-marked. Cellular cartilage is found in the external ears of rats, mice, and some other animals, and is present in the notochord of the human embryo, but is not found in any other human structure. The various cartilages in the body are also classified, according to their functions and positions, into **articular**, **interarticular**, **costal**, and **membraniform**.

Hyaline Cartilage.—Hyaline cartilage consists of a gristly mass of a firm consistence, but of considerable elasticity and pearly bluish color. Except where it coats the articular ends of bones, it is covered externally by a fibrous membrane, the **perichondrium**, from the vessels of which it imbibes its nutritive fluids, being itself destitute of bloodvessels. It contains no nerves. Its intimate structure is very simple. If a thin slice be examined under the microscope, it will be found to consist of cells of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (Fig. 23).

FIG. 23.—Human cartilage cells from the cricoid cartilage
X 350

The cells, when arranged in groups of two or more, have generally straight outlines where they are in contact with each other, and in the rest of their circumference are rounded. They consist of clear translucent protoplasm in which fine interlacing filaments and minute granules are sometimes present; imbedded in this are one or two round nuclei, having the usual intranuclear network. The cells are contained in cavities in the matrix, called **cartilage lacunæ**; around these the matrix is arranged in concentric lines, as if it had been formed in successive portions around the cartilage cells. This constitutes the so-called **capsule of the space**. Each lacuna is generally occupied by a single cell, but during the division of the cells it may contain two, four, or eight cells.

The matrix is transparent and apparently without structure, or else presents a

dimly granular appearance, like ground glass. Some observers have shown that the matrix of hyaline cartilage, and especially of the articular variety, after prolonged maceration, can be broken up into fine fibrils. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the lacunæ with each other, and that these canals communicate with the lymphatics of the perichondrium, and thus the structure is permeated by a current of nutrient fluid.

Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety. They present differences in the size, shape, and arrangement of their cells.

In **Articular Cartilage** (Fig. 24), which shows no tendency to ossification, the matrix is finely granular; the cells and nuclei are small, and are disposed parallel to the surface in the superficial part, while nearer to the bone they are arranged in vertical rows. Articular cartilages have a tendency to split in a vertical direction; in disease this tendency becomes very manifest. The free surface of articular cartilage, where it is exposed to friction, is not covered by perichondrium, although a layer of connective tissue continuous with that of the synovial membrane can be

Bone

FIG. 24.—Vertical section of articular cartilage.

FIG. 25.—Costal cartilage from a man, aged seventy-six years, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell wall. Highly magnified.

traced in the adult over a small part of its circumference, and here the cartilage cells are more or less branched and pass insensibly into the branched connective tissue corpuscles of the synovial membrane. Articular cartilage forms a thin incrustation upon the joint surfaces of the bones, and its elasticity enables it to break the force of concussions, while its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, the reverse being the case on concave articular surfaces. It appears to derive its nutriment partly from the vessels of the neighboring synovial membrane and partly from those of the bone upon which it is implanted. Toyne has shown that the minute vessels of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

In **Costal Cartilage** the cells and nuclei are large, and the matrix has a tendency to fibrous striation, especially in old age (Fig. 25). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears,

at first sight, to be an exception to the statement that cartilage is a non-vascular tissue, but is not so really, for the vessels give no branches to the cartilage substance itself, and the channels may rather be looked upon as involutions of the perichondrium. The xiphoid process and the cartilages of the nose, larynx, and trachea (except the epiglottis and corniculate cartilages of the larynx, which are composed of elastic fibrocartilage) resemble the costal cartilages in microscopic characteristics. The arytenoid cartilage of the larynx shows a transition from hyaline cartilage at its base to elastic cartilage at the apex.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by calcium salts without any appearance of true bone. The process of calcification occurs frequently, in such cartilages as those of the trachea and in the costal cartilages, where it may be succeeded by conversion into true bone.

White Fibrocartilage.—White fibrocartilage consists of a mixture of white fibrous tissue and cartilaginous tissue in various proportions; to the former of these constituents it owes its flexibility and toughness, and to the latter its elasticity. When examined under the microscope it is found to be made up of fibrous connective tissue arranged in bundles, with cartilage cells between the bundles; the cells to a certain extent resemble tendon cells, but may be distinguished from them by being surrounded by a concentrically striated area of cartilage matrix and by being less flattened (Fig. 26). The white fibrocartilages admit of arrangement into four groups—*interarticular*, *connecting*, *circumferential*, and *stratiform*.

FIG. 26.—White fibrocartilage from an intervertebral fibrocartilage.

1. The *Interarticular Fibrocartilages* (*menisci*) are flattened fibrocartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, usually thinner toward the centre than at the circumference, and held in position by the attachment of their margins and extremities to the surrounding ligaments. The synovial membranes of the joints are prolonged over them. They are found in the temporomandibular, sternoclavicular, acromioclavicular, wrist, and knee joints—*i. e.*, in those joints which are most exposed to violent concussion and subject to frequent movement. Their uses are to obliterate the intervals between opposed surfaces in their various motions; to increase the depths of the articular surfaces and give ease to the gliding movements; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these interarticular fibrocartilages serve an important purpose in increasing the varieties of movement in a joint. Thus in the knee joint there are two kinds of motion, *viz.*, angular movement and rotation, although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the interarticular cartilages, the latter between the cartilages and the head of the tibia. So, also, in the temporomandibular joint, the movements of opening and shutting the mouth take place between the fibrocartilage and the mandible, the grinding movement between the mandibular fossa and the fibrocartilage, the latter moving with the mandible.

2. The **Connecting Fibrocartilages** are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebrae. They form disks which are closely adherent to the opposed surfaces. Each disk is composed of concentric rings of fibrous tissue, with cartilaginous laminae interposed, the former tissue predominating toward the circumference, the latter toward the centre.

3. The **Circumferential Fibrocartilages** consist of rims of fibrocartilage, which surround the margins of some of the articular cavities, *e. g.*, the glenoidal labrum of the hip, and of the shoulder; they serve to deepen the articular cavities and to protect their edges.

4. The **Stratiform Fibrocartilages** are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibrocartilage are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the *Peronaeus longus* and *Tibialis posterior*.

Yellow or Elastic Fibrocartilage is found in the human body in the auricles of the external ear, the auditory tubes, the corniculate cartilages of the larynx, and the

epiglottis. It consists of cartilage cells and a matrix, the latter being pervaded by a network of yellow elastic fibres, branching and anastomosing in all directions, except immediately around each cell, where there is a variable amount of non-fibrillated hyaline, intercellular substance (Fig. 27). The fibres resemble those of yellow elastic tissue, both in appearance and in being unaffected by acetic acid; and according to Rollett their continuity with the elastic fibres of the neighboring tissue is demonstrable.

The distinguishing feature of cartilage chemically is that it yields on boiling a substance called **chondria**, very similar to gelatin, but differing from it in several of its reactions. It is now believed that chondrin is not a simple body, but

FIG. 27.—Yellow or elastic fibrocartilage from epiglottis of cat.

a mixture of gelatin with mucinoid substances, chief among which, perhaps, is a compound termed **chondro-mucoid**.

Bone.—Structure and Physical Properties.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its color, in a fresh state, is pinkish-white externally, and deep red within. On examining a section of any bone, it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed **compact tissue**; the other consists of slender fibres and lamellae, which join to form a reticular structure; this, from its resemblance to lattice-work, is called **cancellous tissue**. The compact tissue is always placed on the exterior of the bone, the cancellous in the interior. The relative quantity of these two kinds of tissue varies in different bones, and in different parts of the same bone, according as strength or lightness is requisite. Close examination of the compact tissue shows it to be extremely porous, so that the difference in structure between it and the cancellous tissue depends merely upon the different amount of solid matter, and the size and number of spaces in each; the cavities are small in the compact tissue and the solid matter between

them abundant, while in the cancellous tissue the spaces are large and the solid matter is in smaller quantity.

Bone during life is permeated by vessels, and is enclosed, except where it is coated with articular cartilage, in a fibrous membrane, the **periosteum**, by means of which many of these vessels reach the hard tissue. If the periosteum be stripped from the surface of the living bone, small bleeding points are seen which mark the entrance of the periosteal vessels; and on section during life every part of the bone exudes blood from the minute vessels which ramify in it. The interior of each of the long bones of the limbs presents a cylindrical cavity filled with marrow and lined by a highly vascular areolar structure, called the **medullary membrane** or **internal periosteum**.

Periosteum.—The periosteum adheres to the surface of each of the bones in nearly every part, but not to cartilaginous extremities. When strong tendons or ligaments are attached to a bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer one formed chiefly of connective tissue, containing occasionally a few fat cells; the inner one, of elastic fibres of the finer kind, forming dense membranous networks, which can be again separated into several layers. In young bones the periosteum is thick and very vascular, and is intimately connected at either end of the bone with the epiphysial cartilage, but less closely with the body of the bone, from which it is separated by a layer of soft tissue, containing a number of **granular corpuscles** or **osteoblasts**, by which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner and less vascular, and the osteoblasts are converted into an epithelioid layer on the deep surface of the periosteum. The periosteum serves as a **nidus** for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

Marrow.—The marrow not only fills up the cylindrical cavities in the bodies of the long bones, but also occupies the spaces of the cancellous tissue and extends into the larger bony canals (Haversian canals) which contain the bloodvessels. It differs in composition in different bones. In the bodies of the long bones the marrow is of a *yellow* color, and contains, in 100 parts, 96 of fat, 1 of areolar tissue and vessels, and 3 of fluid with extractive matter; it consists of a basis of connective tissue supporting numerous bloodvessels and cells, most of which are fat cells but some are “marrow cells,” such as occur in the red marrow to be immediately described. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs the marrow is of a *red* color, and contains, in 100 parts, 75 of water, and 25 of solid matter consisting of cell-globulin, nucleoprotein, extractives, salts, and only a small proportion of fat. The red marrow consists of a small quantity of connective tissue, bloodvessels, and numerous cells (Fig. 28), some few of which are fat cells, but the great majority are roundish nucleated cells, the true “marrow cells” of Kölliker. These marrow cells proper, or **myelocytes**, resemble in appearance lymphoid corpuscles, and like them are amoeboid; they generally have a hyaline protoplasm, though some show granules either oxyphil or basiphil in reaction. A number of eosinophil cells are also present. Among the marrow cells may be seen smaller cells, which possess a slightly pinkish hue; these are the **erythroblasts** or **normoblasts**, from which the red corpuscles of the adult are derived, and which may be regarded as descendants of the nucleated colored corpuscles of the embryo. **Giant cells** (*myeloplaxes*, *osteoclasts*), large, multinucleated, protoplasmic masses, are also to be found in both sorts of adult marrow, but more particularly in red marrow. They were believed by Kölliker to be concerned in the absorption of bone matrix, and hence the name which he gave to them—**osteoclasts**. They

excavate in the bone small shallow pits or cavities, which are named *Howship's foveolæ*, and in these they are found lying.

Vessels and Nerves of Bone.—The bloodvessels of bone are very numerous. Those of the compact tissue are derived from a close and dense network of vessels ramifying in the periosteum. From this membrane vessels pass into the minute orifices in the compact tissue, and run through the canals which traverse its substance. The cancellous tissue is supplied in a similar way, but by less numerous and larger vessels, which, perforating the outer compact tissue, are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces; some of these give passage to the arteries of the larger set of vessels referred to; but the most numerous and largest apertures are for some of the veins of the cancellous tissue, which emerge apart from the arteries. The marrow in the body of a long bone is supplied by one large artery (or sometimes more), which enters the bone at the nutrient foramen

(situated in most cases near the centre of the body), and perforates obliquely the compact structure. The *medullary* or *nutrient* artery, usually accompanied by one or two veins, sends branches upward and downward, which ramify in the medullary membrane, and give twigs to the adjoining canals. The ramifications of this vessel anastomose with the arteries of the cancellous and compact tissues. In most of the flat, and in many of the short spongy bones, one or more large apertures are observed, which transmit to the central parts of the bone vessels corresponding to the nutrient arteries and veins. The veins emerge from the long bones in three places (Kölliker): (1) one or two large veins accompany the artery; (2) numerous large and small veins emerge at the articular extremities; (3) many small veins pass out of the compact substance. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in the diploic tissue, the sides of the canals being formed by thin lamellæ of bone, perforated here and there for the passage of branches from the adjacent cancelli. The same condition is also found in all cancellous tissue, the veins being enclosed and supported by osseous

material, and having exceedingly thin coats. When a bone is divided, the vessels remain patulous, and do not contract in the canals in which they are contained. **Lymphatic vessels**, in addition to those found in the periosteum, have been traced by Cruikshank into the substance of bone, and Klein describes them as running in the Haversian canals. **Nerves** are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said by Kölliker to be most numerous in the articular extremities of the long bones, in the vertebræ, and in the larger flat bones.

Minute Anatomy.—A transverse section of dense bone may be cut with a saw and ground down until it is sufficiently thin.

If this be examined with a rather low power the bone will be seen to be mapped out into a number of circular districts each consisting of a central hole surrounded by a number of concentric rings. These districts are termed **Haversian systems**; the central hole is an **Haversian canal**, and the rings are layers of bony tissue arranged concentrically around the central canal, and termed **lamellæ**. Moreover, on closer examination it will be found that between these lamellæ, and therefore also arranged concentrically around the central canal, are a number of

FIG. 29.—Transverse section of compact tissue of bone. Magnified. (Sharpey)

little dark spots, the **lacunæ**, and that these lacunæ are connected with each other and with the central Haversian canal by a number of fine dark lines, which radiate like the spokes of a wheel and are called **canaliculi**. Filling in the irregular intervals which are left between these circular systems are other lamellæ, with their lacunæ and canaliculi running in various directions, but more or less curved (Fig. 29); they are termed **interstitial lamellæ**. Again, other lamellæ, found on the surface of the bone, are arranged parallel to its circumference; they are termed **circumferential**, or by some authors **primary** or **fundamental lamellæ**, to distinguish them from those laid down around the axes of the Haversian canals, which are then termed **secondary** or **special lamellæ**.

The **Haversian canals**, seen in a transverse section of bone as round holes at or about the centre of each Haversian system, may be demonstrated to be true canals if a longitudinal section be made (Fig. 30). It will then be seen that the canals run parallel with the longitudinal axis of the bone for a short distance and then branch and communicate. They vary considerably in size, some being as much as 0.12 mm. in diameter; the average size is, however, about 0.05 mm. Near the medullary cavity the canals are larger than those near the surface of the bone.

Each canal contains one or two bloodvessels, with a small quantity of delicate connective tissue and some nerve filaments. In the larger ones there are also lymphatic vessels, and cells with branching processes which communicate, through the canaliculi, with the branched processes of certain bone cells in the substance of the bone. Those canals near the surface of the bone open upon it by minute orifices, and those near the medullary cavity open in the same way into this space, so that the whole of the bone is permeated by a system of bloodvessels running through the bony canals in the centres of the Haversian systems.

The **lamellæ** are thin plates of bony tissue encircling the central canal, and may be compared, for the sake of illustration, to a number of sheets of paper pasted one over another around a central hollow cylinder. After macerating a piece of bone in dilute mineral acid, these lamellæ may be stripped off in a

FIG. 30.—Section parallel to the surface from the body of the femur. $\times 100$. a, Haversian canals; b, lacunæ seen from the side; c, others seen from the surface in lamellæ, which are cut horizontally.

longitudinal direction as thin films. If one of these be examined with a high power of the microscope, it will be found to be composed of a finely reticular structure, made up of very slender transparent fibres, decussating obliquely; and coalescing at the points of intersection; these fibres are composed of fine fibrils identical with those of white connective tissue. The intercellular matrix between the fibres is impregnated by calcareous deposit which the acid dissolves. In many places the various lamellæ may be seen to be held together by tapering fibres, which run obliquely through them, pinning or bolting them together; they were first described by Sharpey, and were named by him **perforating fibres** (Fig. 31).

The **Lacunæ** are situated between the lamellæ, and consist of a number of oblong spaces. In an ordinary microscopic section, viewed by transmitted light, they appear as fusiform opaque spots. Each lacuna is occupied during life by a branched cell, termed a **bone-cell** or **bone-corpuscle**, the processes from which extend into the canaliculi (Fig. 32).

The **Canaliculi** are exceedingly minute channels, crossing the lamellæ and connecting the lacunæ with neighboring lacunæ and also with the Haversian canal. From the Haversian canal a number of canaliculi are given off, which radiate from it, and open into the first set of lacunæ between the first and second lamellæ. From these lacunæ a second set of canaliculi is given off; these run outward to the

next series of lacunæ, and so on until the periphery of the Haversian system is reached; here the canaliculi given off from the last series of lacunæ do not communicate with the lacunæ of neighboring Haversian systems, but after passing outward for a short distance form loops and return to their own lacunæ. Thus every part of an Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and distributed through the canaliculi and lacunæ.

The bone cells are contained in the lacunæ, which, however, they do not completely fill. They are flattened nucleated branched cells, homologous with those of connective tissue; the branches, especially in young bones, pass into the canaliculi from the lacunæ.

In thin plates of bone (as in the walls of the spaces of cancellous tissue) the Haversian canals are absent, and the canaliculi open into the spaces of the cancellous tissue (medullary spaces), which thus have the same function as the Haversian canals.

Chemical Composition.—Bone consists of an animal and an earthy part intimately combined together.

FIG. 32.—Nucleated bone cells and their processes, contained in the bone lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

Bone corpuscle *Bone corpuscle*
between inter-
stitial lamellæ

FIG. 33.—Transverse section of body of human fibula, decalcified X 250

The animal part may be obtained by immersing a bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. If now a transverse section is made (Fig. 33) the same general arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi is seen.

The earthy part may be separately obtained by calcination, by which the animal matter is completely burnt out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble down with the slightest force. The earthy matter is composed chiefly of calcium phosphate, forming about 66.7 per cent. of the weight

of the bone; it confers on bone its hardness and rigidity, while the animal matter (*ossein*) determines its tenacity.

Ossification.—Some bones are preceded by membrane, such as those forming the roof and sides of the skull; others, such as the bones of the limbs, are preceded by rods of cartilage. Hence two kinds of ossification are described: the **intra-membranous** and the **intracartilaginous**.

INTRAMEMBRANOUS OSSIFICATION.—In the case of bones which are developed in membrane, no cartilaginous mould precedes the appearance of the bony tissue. The membrane which occupies the place of the future bone is of the nature of connective tissue, and ultimately forms the periosteum; it is composed of fibres and granular cells in a matrix. The peripheral portion is more fibrous, while, in the interior the cells or *osteoblasts* predominate; the whole tissue is richly supplied with bloodvessels. At the outset of the process of bone formation a little network of spicules is noticed radiating from the point or centre of ossification. These rays consist at their growing points of a network of fine clear fibres and granular corpuscles with an intervening ground substance (Fig. 34). The fibres are termed

FIG. 34.—Part of the growing edge of the developing parietal bone of a fetal cat. (After J. Lawrence.)

osteogenetic fibres, and are made up of fine fibrils differing little from those of white fibrous tissue. The membrane soon assumes a dark and granular appearance from the deposition of calcareous granules in the fibres and in the intervening matrix, and in the calcified material some of the granular corpuscles or osteoblasts are enclosed. By the fusion of the calcareous granules the tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunæ. As the osteogenetic fibres grow out to the periphery they continue to calcify, and give rise to fresh bone spicules. Thus a network of bone is formed, the meshes of which contain the bloodvessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh layers of bone formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently successive layers of bony tissue are deposited under the periosteum and around the larger vascular channels which become the Haversian canals, so that the bone increases much in thickness.

INTERCARTILAGINOUS OSSIFICATION.—Just before ossification begins the mass is entirely cartilaginous, and in a long bone, which may be taken as an example, the process commences in the centre and proceeds toward the extremities, which for some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually extends through them. The extremities do not, however, become joined to the body of the bone by bony tissue until growth has ceased; between the body and either extremity a layer of cartilaginous tissue termed the **epiphysal cartilage** persists for a definite period.

The first step in the ossification of the cartilage is that the cartilage cells, at the point where ossification is commencing and which is termed a **centre of ossification**, enlarge and arrange themselves in rows (Fig. 35). The matrix in which they are imbedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in this matrix, between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and transverse bars of calcified substance stretch across from one calcareous column to another. Thus there are longitudinal groups of the cartilage cells enclosed in oblong cavities, the walls of which are formed of calcified matrix which cuts off all nutrition from the cells; the cells, in consequence, atrophy, leaving spaces called the **primary areolæ**.

At the same time that this process is going on in the centre of the solid bar of cartilage, certain changes are taking place on its surface. This is covered by a very vascular membrane, the **perichondrium**, entirely similar to the embryonic connective tissue already described as constituting the basis of membrane bone; on the inner surface of this—that is to say, on the surface in contact with the cartilage—are gathered the formative cells, the **osteoblasts**. By the agency of these cells a thin layer of bony tissue is formed between the perichondrium and the cartilage, by the **intramembranous** mode of ossification just described. There are then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, formed of calcified matrix and containing the withered cartilage cells, and on the surface of the cartilage the formation of a layer of true membrane bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium, which has now become periosteum (Fig. 35, *ir*). The processes consist of bloodvessels and

FIG. 35. Section of fetal bone of cat. *ir*, Irruption of the subperiosteal tissue. *p*, Fibrous layer of the periosteum. *o*, Layer of osteoblasts. *im*, Subperiosteal bony deposit. (From Quain's "Anatomy," E. A. Schäfer.)

cells—osteoblasts, or bone-formers, and osteoclasts, or bone-destroyers. The latter are similar to the giant cells (myeloplaxes) found in marrow, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (Fig. 36). Wherever these processes come in contact with the calcified walls of the primary areolæ they absorb them, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the **secondary areolæ** or **medullary spaces**. These secondary spaces become filled with embryonic marrow, consisting of osteoblasts and vessels, derived, in the manner described above, from the osteogenetic layer of the periosteum (Fig. 36).

Thus far there has been traced the formation of enlarged spaces (secondary areolæ), the perforated walls of which are still formed by calcified cartilage matrix, containing an embryonic marrow derived from the processes sent in from the osteogenetic layer of the periosteum, and consisting of bloodvessels and osteoblasts. The walls of these secondary areolæ are at this time of only inconsiderable thickness, but they become thickened by the deposition of layers of true bone on their surface. This process takes place in the following manner: Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as an epithelioid layer on the surface of the wall of the space (Fig. 37). This layer of osteoblasts forms a bony stratum, and thus the wall of the space becomes gradually covered with a layer of

FIG. 36.—Part of a longitudinal section of the developing femur of a rabbit. *a*. Flattened cartilage cells. *b*. Enlarged cartilage cells. *c*, *d*. Newly formed bone. *e*. Osteoblasts. *f*. Oste.

FIG. 37.—Osteoblasts and osteoclasts on trabecula of lower jaw of calf embryo. (Kölliker.)

true osseous substance in which some of the bone-forming cells are included as bone corpuscles. The next stage in the process consists in the removal of these primary bone spicules by the osteoclasts. One of these giant cells may be found lying in a Howship's foveola at the free end of each spicule. The removal of the primary spicules goes on *pari passu* with the formation of permanent bone by the periosteum, and in this way the medullary cavity of the body of the bone is formed.

This series of changes has been gradually proceeding toward the end of the body of the bone, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone at the centre of the body to the hyaline cartilage at the extremities.

While the ossification of the cartilaginous body is extending toward the articular ends, the cartilage immediately in advance of the osseous tissue continues to grow until the length of the adult bone is reached.

During the period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous, then a bony centre appears, and initiates in it the process of intracartilaginous ossification; but this process never extends to any great distance. The epiphysis remains separated from the body by a narrow cartilaginous layer for a definite time. This layer ultimately ossifies, the distinction between body and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to such processes of bone as are separately ossified, *e. g.*, the trochanters of the femur. The bones therefore continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend behind the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place from within, by which the medullary cavities are increased.

The permanent bone formed by the periosteum when first laid down is cancellous in structure. Later the osteoblasts contained in its spaces become arranged in the concentric layers characteristic of the Haversian systems, and are included as bone corpuscles.

The number of ossific centres varies in different bones. In most of the short bones ossification commences at a single point near the centre, and proceeds toward the surface. In the long bones there is a central point of ossification for the body or diaphysis: and one or more for each extremity, the epiphysis. That for the body is the first to appear. The times of union of the epiphyses with the body vary inversely with the dates at which their ossifications began (with the exception of the fibula) and regulate the direction of the nutrient arteries of the bones. Thus, the nutrient arteries of the bones of the arm and forearm are directed toward the elbow, since the epiphyses at this joint become united to the bodies before those at the opposite extremities. In the lower limb, on the other hand, the nutrient arteries are directed away from the knee: that is, upward in the femur, downward in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur, and the lower epiphyses of the tibia and fibula, unite first with the bodies. Where there is only one epiphysis, the nutrient artery is directed toward the other end of the bone; as toward the acromial end of the clavicle, toward the distal ends of the metacarpal bone of the thumb and the metatarsal bone of the great toe, and toward the proximal ends of the other metacarpal and metatarsal bones.

Parsons¹ groups epiphyses under three headings, viz.: (1) **pressure epiphyses**, appearing at the articular ends of the bones and transmitting "the weight of the body from bone to bone;" (2) **traction epiphyses**, associated with the insertion of muscles and "originally sesamoid structures though not necessarily sesamoid bones;" and (3) **atavistic epiphyses**, representing parts of the skeleton, which at one time formed separate bones, but which have lost their function, "and only appear as separate ossifications in early life."

Applied Anatomy.—It has been stated above that the bones increase firstly *in length* by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process; and secondly, *in circumference* by deposition of new bone from the deeper layer of the periosteum, on the external surface.

A careful study of osseous development is of the very greatest utility in the proper understanding of bone disease; and, moreover, an accurate knowledge of the blood supply of a long bone

¹ Jour. of Anat. and Phys., vols. xxxviii, xxxix, and xlii.

has also many important bearings. The outer portion of the compact tissue being supplied by periosteal vessels, which reach the bone through muscular attachments, it follows that where the muscular structures are well developed, and therefore amply supplied with blood, the periosteum will also be well-nourished and the bones proportionately well-developed in girth; this is well seen in strong muscular men with well-marked ridges on the bones. Conversely, if the muscular development be poor, the bones are correspondingly thin and light, and if from any cause a limb has been paralyzed from early childhood, the whole of the bones of that extremity are remarkable for their extreme thinness—that is to say, the periosteal blood supply has been insufficient to nourish that membrane, and consequently very little fresh osseous tissue has been added to the bones from the outside.

The best example of this condition is seen in connection with the disease known as *infantile paralysis*, where a limb becomes paralyzed at a very early period of childhood, where the muscles become flaccid and atonic, and where the blood supply is in consequence very greatly diminished. In such cases, although the limb does continue to grow in length from the epiphysal lines, its length is considerably less than on the normal side, owing to the imperfect nutrition; but the most striking feature about all the long bones of the limb is their remarkable tenuity, little or no addition having been made to their circumferences.

In cases where the periosteum has been separated from the compact tissue by extensive injury or inflammatory exudation, necrosis or death of the underlying portion of bone takes place owing to its blood supply having been cut off, and the dead portion or *sequestrum* has to be separated and subsequently cast off.

Cases, however, occur where the inflammatory process affects the whole or a great portion of the diaphysis of a long bone, and here extensive death of the affected portion takes place, and the condition goes by the name of *acute infective periostitis*. Where this occurs the body of the bone dies very rapidly, especially if the single nutrient artery be thrombosed at the same time. The pus which has formed beneath the periosteum is set free by timely incision, or bursts on the surface; the periosteum then falls back on the necrosed diaphysis and rapidly forms a layer of new periosteal bone, surrounding the sequestrum. This layer is called the *involucrum*, and the openings in it through which the pus escapes the *cloacæ*. When the inflammatory process affects mainly the medullary canal, the condition is spoken of as *osteomyelitis*, and the two conditions very frequently coexist, and then go by the name of *acute infective necrosis of bone* or *acute diaphysitis*. When the medullary cavity is filled with pus, septic thrombosis of the veins in the Haversian canals takes place, and there is a very great danger of septic emboli being displaced and carried into the general circulation, thus setting up a fatal *pyemia*. In fact, pyemia is more frequently due to septic bone conditions than to any other cause.

In the pre-antiseptic days, pyemia frequently resulted from amputations, where the medullary canal of a long bone was opened by the saw cut. Osteomyelitis ensued, and if the patient survived, a tubular sequestrum of the divided shaft subsequently separated.

A proper knowledge of the epiphyses is of the utmost possible importance, and greatly simplifies many of the problems in the pathology of bone disease.

Speaking generally, the long bones have at either end an epiphysis from the cartilage of which growth occurs, and hence the body of the bone increases in length from both ends. In every case, however, one epiphysis is the more active, and also continues in its activity for a longer time. This *actively growing epiphysis* is always the one from which the nutrient foramen in the diaphysis points, and it unites to the diaphysis at a later date. It follows, therefore, that the increase in length of a bone is largely dependent on this epiphysis, and hence anything which interferes with the growth from this epiphysal line at any time prior to the union of the epiphysis with the diaphysis must result in a cessation of growth in length of that bone. Thus when dealing with disease in the neighborhood of this actively growing epiphysis very great care should be taken not to excise or destroy its line of union with the diaphysis. These epiphyses are particularly prone to become the seat of tuberculous disease, which especially tends to attack the soft, highly vascular cancellous tissue.

Again, the actively growing epiphysal plate is the portion of a long bone which is in the vast majority of cases affected by tumor growth in bone, whether it be innocent or malignant, the former (*e. g.*, osteoma) usually appearing about puberty, and the latter (*e. g.*, sarcoma) usually toward the end of the active period of epiphysal growth.

Epiphysal growth, moreover, has to be considered by the surgeon when he is about to amputate in a child. If the amputation is being performed through a bone, the actively growing epiphysis of which is at the upper end, and which will continue to grow for several years (*e. g.*, humerus and tibia), it will be necessary to make allowance for this and to cut the flaps long; as otherwise, owing to continued growth, the sawn end of the bone will ultimately project through the stump, and a condition known as "conical stump" will result. This requires removal of a further portion of the bone.

An inflammatory condition termed *acute epiphysitis* also occurs, although it is not so frequent as the acute infective conditions of the diaphysis, owing to the freer blood supply of the epiphysis;

in late years it has been shown that acute epiphysitis in children is very frequently the result of a pneumococcal infection, and it may pass on to complete separation of the epiphysis. In this connection it is worthy of note that some of the epiphysial lines lie entirely within the capsules of their corresponding joints, in other cases entirely without the capsules; and it must follow that in the former case epiphysial disease, acute or chronic, becomes, *ipso facto*, practically synonymous with disease of that joint. The best examples of intra-articular epiphyses are those for the head of the femur and head of the humerus, and the vast majority of all cases of tuberculous disease of the hip start as a tuberculous epiphysitis about the intra-articular epiphysial plate of the femur; again cases of acute septic arthritis of the shoulder or hip joints generally have their origins in these intra-articular epiphysial lines, and often result in separation of the affected epiphysis. Those of the other class, or extra-articular epiphyses, when diseased, do not tend to involve the neighboring joint so readily; and it should be the surgeon's duty to keep the disease from involving the joint. For example, the trochanteric epiphysis of the femur is extra-articular as regards the hip-joint, and the epiphysial line of the head of the tibia is well below the level of the knee-joint, and should a chronic tuberculous abscess form in the latter situation, it should be attacked from the outside before it has time to spread up and involve the cartilage of the head of the tibia. It is therefore of great surgical interest to note in every case the relations which the various epiphysial lines bear to their respective joint capsules.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medicolegal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the diaphysis, and such injuries may be mistaken for fracture or dislocation.

THE CIRCULATING FLUIDS.

The circulating fluids of the body are the **blood** and the **lymph**.

Blood.—The blood is an opaque, rather viscid fluid, of a bright red or scarlet color when it flows from the arteries, of a dark red or purple color when it flows from the veins. It is salt to the taste, and has a peculiar faint odor and an alkaline reaction. Its specific gravity is about 1.06, and its temperature is generally about 37° C., though varying slightly in different parts of the body.

General Composition of the Blood.—Blood consists of a faintly yellow fluid, the **plasma** or **liquor sanguinis**, in which are suspended numerous minute particles, the **blood corpuscles**, the majority of which are colored and give to the blood its red tint. If a drop of blood be placed in a thin layer on a glass slide and examined under the microscope, a number of these corpuscles will be seen floating in the plasma.

The **Blood Corpuscles** are of three kinds: (1) colored corpuscles or **erythrocytes**; (2) colorless corpuscles or **leucocytes**; (3) blood platelets.

1. **Colored or red corpuscles (erythrocytes)**, when examined under the microscope, are seen to be circular disks, biconcave in profile. The disk has no nucleus, but, in consequence of its biconcave shape, presents, according to the alterations of focus under an ordinary high power, a central part, sometimes bright, sometimes dark, which has the appearance of a nucleus (Fig. 38, *a*). It is to the aggregation of the red corpuscles that the blood owes its red hue, although when examined by transmitted light their color appears to be only a faint reddish yellow. The corpuscles vary slightly in size even in the same drop of blood, but the average

FIG. 38. Human red blood corpuscles. Highly magnified. *a*. Seen from the surface. *b*. Seen in profile and forming rouleaux. *c*. Rendered spherical by water. *d*. Rendered crenate by salt solution.

diameter of each is about 7.5μ ,¹ and the thickness about 2μ . Besides these there are found certain smaller corpuscles of about one-half of the size just indicated; these are termed **microcytes**, and are very scarce in normal blood; in diseased conditions (*e. g.*, anemia), however, they are more numerous. The number of red corpuscles in the blood is enormous; between 4,000,000 and 5,000,000 are contained in a cubic millimetre. Power states that the red corpuscles of an adult would present an aggregate surface of about 3000 square yards.

If the web of a living frog's foot be spread out and examined under the microscope the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when human blood is drawn and examined on a slide without reagents the corpuscles tend to collect into heaps like rouleaux of coins (Fig. 38, *b*). It has been suggested that this phenomenon may be explained by alteration in surface tension. During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves, to some extent, to the size of the vessel. They are, however, highly elastic, and speedily recover their shape when the pressure is removed. They are readily influenced by the medium in which they are placed. In water they swell up, lose their shape, and become globular (*endosmosis*) (Fig. 38, *c*). Subsequently the hemoglobin is dissolved out, and the envelope can barely be distinguished as a faint circular outline. Solutions of salt or sugar, denser than the plasma, give them a stellate or crenated appearance (*exosmosis*) (Fig. 38, *d*), but the usual shape may be restored by diluting the solution to the same tonicity as the plasma. The crenated outline may be produced as the first effect of the passage of an electric shock: subsequently, if sufficiently strong, the shock ruptures the envelope. A solution of salt, isotonic with the plasma, merely separates the blood corpuscles mechanically, without changing their shape. Two views are held with regard to the structure of the erythrocytes. The older view, that of Rollett, supposes that the corpuscle consists of a sponge work or stroma permeated by a solution of hemoglobin. Schäfer, on the other hand, believes that the hemoglobin solution is contained within an envelope or membrane, and the facts stated above with regard to the osmotic behavior of the erythrocyte support this belief. The envelope consists mainly of lecithin, cholesterin, and nucleoprotein.

The **colorless corpuscles** or **leucocytes** are of various sizes, some no larger, others smaller, than the red corpuscles. In human blood, however, the majority are rather larger than the red corpuscles, and measure about 10μ in diameter. On the average from 7000 to 12,000 leucocytes are found in each cubic millimetre of blood.

They consist of minute masses of nucleated protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm, and by the staining reactions of these granules when present (Fig. 39). (1) The most numerous (60 per cent.) and important are irregular in shape, possessed of the power of amoeboid movement, and are characterized by nuclei which often consist of two or three parts (multipartite) connected together by fine threads of chromatin. The protoplasm is clear, and contains a number of very fine granules, which stain with acid dyes, such as eosin, or with neutral dyes, and are therefore called **oxyphil** or **neutrophil** (Fig. 39, *P*). These cells are termed the **polymorphonuclear leucocytes**. (2) A second variety comprises from 1 to 4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of coarsely granular protoplasm, the granules being highly refractile and grouped around single nuclei of horse-shoe shape (Fig. 39, *E*). The granules stain deeply with eosin, and the cells are there-

¹ A micromillimetre (μ) is 1/1000 of a millimetre or 1/25000 of an inch.

40 mm. Their breadth varies in man from 0.01 to 0.1 mm. As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, they may be seen to divide into several branches. In the substance of the muscle, the fibres end by tapering extremities which are joined to the ends of other fibres by the sarcolemma. At the tendinous end of the muscle the sarcolemma appears to blend with a small bundle of fibres, into which the tendon becomes subdivided, while the muscular substance ends abruptly and can be readily made to retract from the point of junction. The areolar tissue between the fibres appear to be prolonged more or less into the tendon, so as to form a kind of sheath around the tendon bundles for a longer or shorter distance. When muscular fibres are attached to skin or mucous membranes, their fibres become continuous with those of the areolar tissue.

FIG. 42.—Transverse section of human striped muscle fibres.
× 255.

FIG. 43.—Striped muscle fibres from tongue of cat. × 250.

The **sarcolemma**, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it sometimes remains entire when the included substance is ruptured. On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in frogs, elongated nuclei are seen, and in connection with these is a little granular protoplasm.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be marked by alternate light and dark bands or striæ, which pass transversely across the fibre (Fig. 43). When examined by polarized light the dark bands are found to be doubly refracting (anisotropic), while the clear stripes are singly refracting (isotropic). The dark and light bands are of nearly equal breadth, and alternate with great regularity; they vary in breadth from about 1 to 2 μ . If the surface be carefully focussed, rows of granules will be detected at the points of junction of the dark and light bands, and very fine longitudinal lines may be seen running through the dark bands and joining these granules together. By treating the specimen with certain reagents (*e. g.*, chloride of gold) fine lines may be seen running transversely between the granules and uniting them together. This appearance is believed to be due to a reticulum or network of interstitial substance lying between the contractile portions of the muscle. The longitudinal striation gives the fibre the appearance of being made up of a bundle of fibrils which have been termed **sarcostyles** or **muscle columns**, and if the fibre be hardened in alcohol, it can be broken up longitudinally and the sarcostyles separated from each other (Fig. 44.) The reticulum, with its longitudinal and transverse meshes, is called **sarcoplasm**.

In a transverse section, the muscular fibre is seen to be divided into a number of areas, called the **areas of Cohnheim**, more or less polyhedral in shape and consisting of the transversely divided sarcostyles, surrounded by transparent sarcoplasm (Fig. 42).

Upon closer examination, and by somewhat altering the focus, the appearances become more complicated, and are susceptible of various interpretations. The

transverse striation, which in Fig. 43 appears as a mere alternation of dark and light bands, is resolved into the appearance seen in Fig. 44, which shows a series of broad dark bands, separated by light bands, each of which is divided into two by a dark dotted line. This line is termed **Dobie's line** or **Krause's membrane** (Fig. 45, *k*), because it was believed by Krause to be an actual membrane, continuous with the sarcolemma, and dividing the light band into two compartments. In addition to the membrane of Krause, fine clear lines may be made out, with a sufficiently high power, crossing the centre of the dark band; these are known as the **lines of Hensen** (Fig. 45, *H*).

FIG. 44.—*A* Portion of a medium-sized human muscular fibre. Magnified nearly 800 diameters. *B*. Separated bundles of fibrils, equally magnified. *a, a*. Larger, and *b, b*, smaller collections. *c*. Still smaller. *d, d*. The smallest which could be detached.

purpose on account of the large amount of interstitial sarcoplasm which separates the sarcostyles. In the following description that given by Schäfer will be closely followed.

Schäfer has worked out the minute anatomy of muscular fibre, particularly in the wing muscles of insects, which are peculiarly adapted for this

FIG. 45.—Diagram of a sarcomere. (After Schäfer) *A*. In moderately extended condition. *B*. In a contracted condition. *k, k*. Membranes of Krause. *H*. Line or plane of Hensen. *S.E.* Poriferous sarcolemmal element.

A sarcostyle may be said to be made up of successive portions, each of which is termed a **sarcomere**. The sarcomere is situated between two membranes of Krause and consists of (1) a central dark part, which forms a portion of the dark band of the whole fibre, and is named a **sarcous element**. This sarcous element really consists of two parts, superimposed one on the top of the other, and when the fibre is stretched these two parts become separated from each other at the line of Hensen

(Fig. 45, A). (2) On either side of this central dark portion is a clear layer, most visible when the fibre is extended; this is situated between the dark centre and the membrane of Krause, and when the sarcomeres are joined together to form the sarcostyle, constitutes the light band of the striated muscular fibre.

When the sarcostyle is extended, the clear intervals are well-marked and plainly to be seen; when, on the other hand, the sarcostyle is contracted, that is to say, when the muscle is in a state of contraction, these clear portions are very small or they may have disappeared altogether (Fig. 45, B). When the sarcostyle is stretched to its full extent, not only is the clear portion well-marked, but the dark portion—the sarcous element—is separated into its two constituents along the line of Hensen. The sarcous element does not lie free in the sarcomere, for when the sarcostyle is stretched, so as to render the clear portion visible, very fine lines, which are probably septa, may be seen running through it from the sarcous element to the membrane of Krause.

Schäfer explains these phenomena in the following way: He considers that each sarcous element is made up of a number of longitudinal channels, which open into the clear part toward the membrane of Krause but are closed at the line of Hensen. When the muscular fibre is contracted the *clear* part of the muscular substance is driven into these channels or tubes, and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere. When, on the other hand, the fibre is extended, this clear substance is driven out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

If this view be true, it is a matter of great interest, and, as Schäfer has shown, harmonizes the contraction of muscle with the amœboid action of protoplasm. In an amœboid cell, there is a framework of spongioplasm, which stains with hematoxylin and similar reagents, enclosing in its meshes a clear substance, hyaloplasm, which will not stain with these reagents. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out as in the formation of pseudopodia. In muscle there is the same thing, viz., a framework of spongioplasm staining with hematoxylin—the substance of the sarcous element—and this encloses a clear hyaloplasm, the clear substance of the sarcomere, which resists staining with this reagent. During contraction of the muscle—*i. e.*, stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—*i. e.*, when there is no stimulation—it tends to pass out of the spongioplasm.

In this way the contraction is brought about: under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

Vessels and Nerves of Striped Muscle.—The capillaries of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. In the red muscles of the rabbit dilatations occur on the transverse branches of the capillary network. The larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi. Nerves are profusely distributed to striped muscle. Their mode of termination is described on page 803. The existence of lymphatic vessels in striped muscle has not been ascertained, though they have been found in tendons and in the sheaths of the muscles.

Unstriped, Plain, or Involuntary Muscle.—Unstriped, plain, or involuntary muscle is found in the following situations: in the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi;

in the gall-bladder and common bile duct; in the large ducts of the salivary and pancreatic glands; in the pelvis and calices of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz., the ovary, the uterine tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the corpora cavernosa of the clitoris; in the male sexual organs—viz., the dartos of the scrotum, the ductus deferens and epididymis, the vesiculæ seminales, the prostate, and the corpora cavernosa of the penis and urethra; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the Arrectores pilorum, and also in the sweat glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

Plain or unstriped muscle is made up of spindle-shaped cells, called **contractile fibre cells**, collected into bundles and held together by a cement substance (Fig. 46). These bundles are further aggregated into larger fasciculi, or flattened bands, and bound together by ordinary connective tissue.

The **contractile fibre cells** are elongated, spindle-shaped, nucleated cells of various sizes, averaging from 40 to 80 μ in length, and 6 to 7 μ in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure. Each presents a faint longitudinal striation and consists of an elastic cell wall containing a central bundle of fibrillæ, representing the contractile substance, and an oval or rod-like nucleus, which includes, within a membrane, a fine net-work communicating at the poles of the nucleus with the contractile fibres (Klein). The fibres are attached to one another by a certain amount of interstitial cement substance which reduces nitrate of silver, but in some regions, *e. g.*, the muscular coats of the intestines, the muscle cells are also connected by "bridges" similar to those which occur in the prickle cells of the epidermis. Unstriped muscle, except the ciliary muscle, is not under the control of the will, neither is the contraction rapid nor does it, as a rule, involve the whole muscle, as is the case with the voluntary muscles. The membranes which are composed of unstriped muscle slowly contract in a part of their extent, generally under the influence of a mechanical stimulus, as that of distension or of cold; and then the contracted part slowly relaxes while another portion of the membrane takes up the contraction. This peculiarity of action is most strongly marked in the intestines, constituting their **vermicular motion**.

FIG. 46.—Muscle fibres from small intestine. (Schäfer.) A. Complete cell. B. Broken cell showing delicate external layer.

Cardiac Muscular Tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are smaller by one-third, and their transverse striæ are by no means so well-marked. They show faint longitudinal striation. The fibres are made up of distinct quadrangular cells, joined end to end so as to form a syncytium (Fig. 47). Each cell contains a clear oval nucleus, situated near its centre. The extremities of the cells have a tendency to branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

Purkinje Fibres (Fig. 48).—Between the endocardium and the ordinary cardiac muscle are found, imbedded in a small amount of connective tissue, peculiar fibres known as **Purkinje fibres**. They are found in certain mammals and in birds, and can be best seen in the sheep's heart, where they form a considerable portion of the moderator band and also appear as gelatinous-looking strands on the inner walls of the atria and ventricles. They also occur in the human heart associated with the terminal distributions of the bundle of His (see p. 614). The fibres are very much larger in size than the cardiac cells and differ from them in several ways. In longitudinal section they are quadrilateral in shape, being about twice as long as they are broad. The central portion of each fibre contains one or more nuclei and is made up of granular protoplasm, with no indication of striations, while the peripheral portion is clear and has distinct transverse striations. The fibres are intimately connected with each other, possess no definite sarcolemma, and do not branch.

FIG. 47.—Anastomosing muscular fibres of the heart seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically.

FIG. 48.—Purkinje fibres from the sheep's heart.

The **Bundle of His** (see p. 614) is composed of cells which differ from ordinary cardiac muscle cells in being more spindle-shaped. They are, moreover, more loosely arranged and have a richer vascular supply than the rest of the heart muscle.

Development of Muscle Fibres.—Voluntary muscular fibres are developed from the mesoderm, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibres, spreads around the circumference, and ultimately extends to the centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of involuntary muscle the mesodermal cell assumes a pointed shape at the extremities and becomes flattened, the nucleus also lengthening out to its permanent rod-like form.

THE NERVOUS TISSUE.

The nervous tissues of the body comprise the brain, the medulla spinalis or spinal cord, the cerebral, spinal, and sympathetic nerves, and the ganglia connected with them.

The nervous tissues are composed of **nerve cells** and their various processes, together with a supporting tissue called **neuroglia**, which, however, is found only in the brain and medulla spinalis. Certain long processes of the nerve cells are of special importance, and it is convenient to consider them apart from the cells; they are known as **nerve fibres**.

To the naked eye a difference is obvious between certain portions of the brain and medulla spinalis, viz., the **gray substance** and the **white substance**. The gray substance is largely composed of nerve cells, while the white substance contains only their long processes, the nerve fibres. It is in the former that nervous impressions are received, stored, and transformed into efferent impulses, and by the latter that they are conducted. Hence the gray substance forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the brain and medulla spinalis; while the white substance forms the bulk of the commissural portions of the nerve centres and the peripheral nerves.

FIG. 49.—Neuroglia cells of brain shown by Golgi's method. (After Andriessen.) A. Cell with branched processes B. Spider cell with unbranched processes.

Neuroglia.—Neuroglia, the peculiar ground substance in which are imbedded the true nervous constituents of the brain and medulla spinalis, consists of cells and fibres. Some of the cells are stellate in shape, with ill-defined cell body, and their fine processes become neuroglia fibres, which extend radially and unbranched (Fig. 49, B) among the nerve cells and fibres which they aid in supporting. Other cells give off fibres which branch repeatedly (Fig. 49, A). Some of the fibres start from the epithelial cells lining the ventricles of the brain and central canal of the medulla spinalis, and pass through the nervous tissue, branching repeatedly to end in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function but is not so in development; it is ectodermal in origin, whereas all connective tissues are mesodermal.

Nerve Cells (Fig. 50).—Nerve cells are largely aggregated in the gray substance of the brain and medulla spinalis, but smaller collections of these cells also form the swellings, called ganglia, seen on many nerves. These latter are found chiefly upon the spinal and cerebral nerve roots and in connection with the sympathetic nerves.

The nerve cells vary in shape and size, and have one or more processes. They may be divided for purposes of description into three groups, according to the number of processes which they possess: (1) **Unipolar cells**, which are found in the spinal ganglia; the single process, after a short course, divides in a T-shaped

manner (Fig. 50, *E*). (2) **Bipolar cells**, also found in the spinal ganglia (Fig. 51), when the cells are in an embryonic condition. They are best demonstrated in the spinal ganglia of fish. Sometimes the processes come off from opposite poles of

FIG. 51.—Bipolar nerve cell from the spinal ganglion of the pike. (After Kölliker.)

characterized by their large size and by the numerous processes which issue from them. The processes are of two kinds: one of them is termed the **axis-cylinder process** or **axon** because it becomes the axis-cylinder of a nerve fibre

the cell, and the cell then assumes a spindle shape; in other cells both processes emerge at the same point. In some cases where two fibres are apparently connected with a cell, one of the fibres is really derived from an adjoining nerve cell and is passing to end in a ramification around the ganglion cell, or, again, it may be coiled spirally around the nerve process which is issuing from the cell. (3) **Multipolar cells**, which are pyramidal or stellate in shape, and

(Figs. 52, 53, 54). The others are termed the **protoplasmic processes** or **dendrons**: they begin to divide and subdivide as soon as they emerge from the cell, and finally end in minute twigs and become lost among the other elements of the nervous tissue.

The body of the nerve cell, known as the **cyton**, consists of a finely fibrillated protoplasmic material, of a reddish or yellowish-brown color, which occasionally presents patches of a deeper tint, caused by the aggregation of pigment granules at one side of the nucleus, as in the substantia nigra and locus caeruleus of the brain. The protoplasm also contains peculiar angular granules, which stain deeply

FIG. 53.—Pyramidal cell from the cerebral cortex of a mouse (After Ramón y Cajal.)

FIG. 54.—Cell of Purkinje from the cerebellum. Golgi method. (Cajal.) a. Axon. b. Collateral. c and d. Dendrons.

with basic dyes, such as methylene blue; these are known as **Nissl's granules** (Fig. 52). They extend into the dendritic processes but not into the axis-cylinder; the small clear area at the point of exit of the axon is termed the **cone of origin**. These granules disappear (*chromatolysis*) during fatigue or after prolonged stimulation of the nerve fibres connected with the cells. They are supposed to represent a store of nervous energy, and in various mental diseases are deficient or absent. The nucleus is, as a rule, a large, well-defined, spherical body, often presenting an intranuclear network, and containing a well-marked nucleolus.

In addition to the protoplasmic network described above, each nerve cell may be shown to have delicate neurofibrils running through its substance (Fig. 55); these fibrils are continuous with the fibrils of the axon, and are believed to convey nerve impulses. Golgi has also described an extracellular network, which is probably a supporting structure.

Nerve Fibres.—Nerve fibres are found universally in the peripheral nerves and in the white substance of the brain and medulla spinalis. They are of two kinds—viz., **medullated** or **white fibres**, and **non-medullated** or **gray fibres**.

FIG. 55.—Nerve cells of kitten, showing neurofibrils. (Cajal.) a. Axon. b. Cyton. c. Nucleus. d. Neurofibrils.

The **medullated fibres** form the white part of the brain and medulla spinalis, and also the greater part of every cerebral and spinal nerve, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body each fibre presents, when examined by transmitted light, a double outline or contour, as if consisting of two parts (Fig. 56). The central portion is named the **axis-cylinder**; around this is a sheath of fatty material, staining black with osmic acid, named the **white substance of Schwann** or **medullary sheath**, which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the **neurolemma**, **primitive sheath**, or **nucleated sheath of Schwann** (Fig. 58).

The **axis-cylinder** is the essential part of the nerve fibre, and is always present; the **medullary sheath** and the **neurolemma** are occasionally absent, especially at the origin and termination of the nerve fibre. The axis-cylinder undergoes no interruption from its origin in the nerve centre to its peripheral termination, and

must be regarded as a direct prolongation of a nerve cell. It constitutes about one-half or one-third of the nerve fibre, being greater in proportion in the fibres of the central organs than in those of the nerves. It is quite transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils, which stain darkly with gold chloride

FIG. 56.—Medullated nerve fibres. (Bidder and Volkmann.)

FIG. 57. Longitudinal and transverse sections of medullated nerve fibre of frog, showing node of Ranvier, medullary segments and fibrils of axis cylinder. Osmic acid. (Biedermann.)

FIG. 58.—Diagram of medullated nerve fibres stained with osmic acid. $\times 425$. (Schäfer) R. Nodes of Ranvier. a. Neurolemma. c. Nucleus.

(Fig. 57), and at its termination may be seen to break up into these fibrillæ. The fibrillæ have been termed the **primitive fibrillæ of Schultz**. The axis-cylinder is said by some to be enveloped in a special reticular sheath, which separates it from the medullary sheath, and is composed of a substance called **neurokeratin**. The more common opinion is that this network or reticulum is contained in the white

matter of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it.

The **medullary sheath**, or **white matter of Schwann** (Fig. 57), is regarded as being a fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis-cylinder. It varies in thickness, in some forming a layer of extreme thinness, so as to be scarcely distinguishable, in others forming about one-half the nerve fibre. The variation in diameter of the nerve fibres (from 2 to 16 μ) depends mainly upon the amount of the white substance, though the axis cylinder also varies within certain limits. The medullary sheath undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points: these are known as the **nodes of Ranvier** (Figs. 57 and 58). The portion of nerve fibre between two nodes is called an **internodal segment**. The **neurolemma** or **primitive sheath** is not interrupted at the nodes, but passes over them as a continuous membrane. If the fibre be treated with silver nitrate the reagent penetrates the neurolemma at the nodes, and on exposure to light reduction takes place, giving rise to the appearance of black crosses, **Ranvier's crosses**, on the axis-cylinder. There may also be seen transverse lines beyond the nodes termed

FIG. 59.—Medullated nerve fibres stained with silver nitrate.

FIG. 60.—A small nervous branch from the sympathetic of a mammal.
a. Two medullated nerve fibres among a number of gray nerve fibres, b.

Frommann's lines (Fig. 59); the significance of these is not understood. In addition to these interruptions oblique clefts may be seen in the medullary sheath, subdividing it into irregular portions, which are termed **medullary segments**, or **segments of Lantermann** (Fig. 57); there is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve fibres, when examined in the fresh condition, frequently present a beaded or varicose appearance: this is due to manipulation and pressure causing the oily matter to collect into drops; and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane.

The **neurolemma** or **primitive sheath** presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier, one nucleus generally lying in the centre of each internode. The primitive sheath is not present in all medullated nerve fibres, being absent in those fibres which are found in the brain and medulla spinalis.

Wallerian Degeneration.—When nerve fibres are cut across, the central ends of the fibres degenerate as far as the first node of Ranvier; but the peripheral ends degenerate simultaneously throughout their whole length. The axons break up into fragments and become surrounded by drops of fatty substance which are formed from the breaking down of the medullary sheath. The nuclei of the primitive sheath proliferate, and finally absorption of the axons and fatty substance occurs. If the cut ends of the nerve be sutured together regeneration of the nerve fibres takes place by the downgrowth of axons from the central end of the nerve. At one time it was believed that the regeneration was peripheral in origin, but this has been disproved, the proliferated nuclei in the peripheral portions taking part merely in the formation of the so-called scaffolding along which the new axons pass.

Non-medullated Fibres.—Most of the fibres of the sympathetic system, and some of the cerebrospinal, consist of the **gray** or **gelatinous nerve fibres** (*fibres of Remak*) (Fig. 60). Each of these consists of an axis-cylinder to which nuclei are applied at intervals. These nuclei are believed to be in connection with a delicate sheath corresponding with the neurolemma of the medullated nerve fibre. In external appearance the non-medullated nerve fibres are semitransparent and gray or yellowish gray. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

EMBRYOLOGY.

THE term **Embryology**, in its widest sense, is applied to the various changes which take place during the growth of an animal from the egg to the adult condition: it is, however, usually restricted to the phenomena which occur before birth. Embryology may be studied from two aspects: (1) that of **ontogeny**, which deals only with the development of the individual; and (2) that of **phylogeny**, which concerns itself with the evolutionary history of the animal kingdom.

In vertebrate animals the development of a new being can only take place when a female germ cell or **ovum** has been fertilized by a male germ cell or **spermatozoön**. The ovum is a nucleated cell, and all the complicated changes by which the various tissues and organs of the body are formed from it, after it has been fertilized, are the result of two general processes, viz., **segmentation** and **differentiation** of cells. Thus, the fertilized ovum undergoes repeated segmentation into a number of cells which at first closely resemble one another, but are, sooner or later, differentiated into two groups: (1) **somatic cells**, the function of which is to build up the various tissues of the body; and (2) **germinal cells**, which become imbedded in the sexual glands—the ovaries in the female and the testes in the male—and are destined for the perpetuation of the species.

Having regard to the main purpose of this work, it is impossible, in the space available in this section, to describe fully, or illustrate adequately, all the phenomena which occur in the different stages of the development of the human body. Only the principal facts are given, and the student is referred for further details to one or other of the text-books¹ on human embryology.

THE OVUM.

The ova are developed from the primitive germ cells which are imbedded in the substance of the ovaries. Each primitive germ cell gives rise, by repeated divisions, to a number of smaller cells termed **oögonia**, from which the **ova** or **primary oöcytes** are developed.

Human ova are extremely minute, measuring about 0.2 mm. in diameter, and are enclosed within the egg follicles of the ovaries; as a rule each follicle contains a single ovum, but sometimes two or more are present.² By the enlargement and subsequent rupture of a follicle at the surface of the ovary, an ovum is liberated and conveyed by the uterine tube to the cavity of the uterus. Unless it be fertilized it undergoes no further development and is discharged from the uterus, but if fertilization take place it is retained within the uterus and is developed into a new being.

In appearance and structure the ovum (Fig. 61) differs little from an ordinary cell, but distinctive names have been applied to its several parts; thus, the cell substance is known as the **yolk** or **oöplasm**, the nucleus as the **germinal vesicle**, and the nucleolus as the **germinal spot**. The ovum is enclosed within a thick, trans-

¹ *Manual of Human Embryology*, Keibel and Mall; *Handbuch der vergleichenden und experimentellen Entwicklungslehre der Wirbeltiere*, Oskar Hertwig; *Lehrbuch der Entwicklungsgeschichte*, Bonnet; *The Physiology of Reproduction*, Marshall.

² See description of the ovary on a future page.

parent envelope, the *zona striata* or *zona pellucida*, adhering to the outer surface of which are several layers of cells, derived from those of the follicle and collectively constituting the *corona radiata*.

Yolk.—The yolk comprises (1) the **cytoplasm** of the ordinary animal cell with its spongioplasm and hyaloplasm; this is frequently termed the **formative yolk**; (2) the **nutritive yolk** or **deutoplasm**, which consists of numerous rounded granules of fatty and albuminoid substances imbedded in the cytoplasm. In the mammalian ovum the nutritive yolk is extremely small in amount, and is of service in nourishing the embryo in the early stages of its development only, whereas in the egg of the bird there is sufficient to supply the chick with nutriment throughout

FIG. 61.—Human ovum examined fresh in the liquor folliculi (Waldeyer.) The *zona pellucida* is seen as a thick clear girdle surrounded by the cells of the *corona radiata*. The egg itself shows a central granular deutoplasmic area and a peripheral clear layer, and encloses the germinal vesicle, in which is seen the germinal spot.

the whole period of incubation. The nutritive yolk not only varies in amount, but in its mode of distribution within the egg; thus, in some animals it is almost uniformly distributed throughout the cytoplasm; in some it is centrally placed and is surrounded by the cytoplasm; in others it is accumulated at the lower pole of the ovum, while the cytoplasm occupies the upper pole. A **centrosome** and **centriole** are present and lie in the immediate neighborhood of the nucleus.

Germinal Vesicle.—The germinal vesicle or nucleus is a large spherical body which at first occupies a nearly central position, but becomes eccentric as the growth of the ovum proceeds. Its structure is that of an ordinary cell-nucleus, viz., it consists of a reticulum or karyomitome, the meshes of which are filled with

karyoplasm, while connected with, or imbedded in, the reticulum are a number of chromatin masses or chromosomes, which may present the appearance of a skein or may assume the form of rods or loops. The nucleus is enclosed by a delicate nuclear membrane, and contains in its interior a well-defined nucleolus or germinal spot.

Coverings of the Ovum.—The *zona striata* or *zona pellucida* (Fig. 61) is a thick membrane, which, under the higher powers of the microscope, is seen to be radially striated. It persists for some time after fertilization has occurred, and may serve for protection during the earlier stages of segmentation. It is not yet determined whether the *zona striata* is a product of the cytoplasm of the ovum or of the cells of the *corona radiata*, or both.

The *corona radiata* (Fig. 61) consists of two or three strata of cells; they are derived from the cells of the follicle, and adhere to the outer surface of the *zona striata* when the ovum is set free from the follicle; the cells are radially arranged around the *zona*, those of the innermost layer being columnar in shape. The cells of the *corona radiata* soon disappear; in some animals they secrete, or are replaced by, a layer of adhesive protein, which may assist in protecting and nourishing the ovum.

The phenomena attending the discharge of the ova from the follicles belong more to the ordinary functions of the ovary than to the general subject of embryology, and are therefore described with the anatomy of the ovaries.¹

FIG. 62.—Formation of polar bodies in *Asterias glacialis*. (Slightly modified from Hertwig.) In I the polar spindle (*sp*) has advanced to the surface of the egg. In II a small elevation (*pb¹*) is formed which receives half of the spindle. In III the elevation is constricted off, forming the first polar body (*pb¹*), and a second spindle is formed. In IV is seen a second elevation which in V has been constricted off as the second polar body (*pb²*). Out of the remainder of the spindle (*f.pn* in VI) the female pronucleus is developed.

Maturation of the Ovum.—Before an ovum can be fertilized it must undergo a process of maturation or ripening. This takes place previous to or immediately after its escape from the follicle, and consists essentially of an unequal subdivision of the ovum (Fig. 62) first into two and then into four cells. Three of the four cells are small, incapable of further development, and are termed **polar bodies** or **polocytes**, while the fourth is large, and constitutes the **mature ovum**. The process of maturation has not been observed in the human ovum, but has been carefully studied in the ova of some of the lower animals, to which the following description applies.

It was pointed out on page 35 that the number of chromosomes found in the nucleus is constant for all the cells in an animal of any given species, and that in man the number is probably twenty-four. This applies not only to the somatic

¹ See description of the ovary on a future page.

cells but to the primitive ova and their descendants. For the purpose of illustrating the process of maturation a species may be taken in which the number of nuclear chromosomes is four (Fig. 36). If an ovum from such be observed at the beginning of the maturation process it will be seen that the number of its chromosomes is apparently reduced to two. In reality, however, the number is doubled, since each chromosome consists of four granules grouped to form a **tetrad**. During the metaphase (see page 36) each tetrad divides into two **dyads**, which are equally distributed between the nuclei of the two cells formed by the first division of the ovum. One of the cells is almost as large as the original ovum, and is named the **secondary oöcyte**; the other is small, and is termed the **first polar body**. The secondary oöcyte now undergoes subdivision, during which each dyad divides and contributes a single chromosome to the nucleus of each of the two resulting cells.

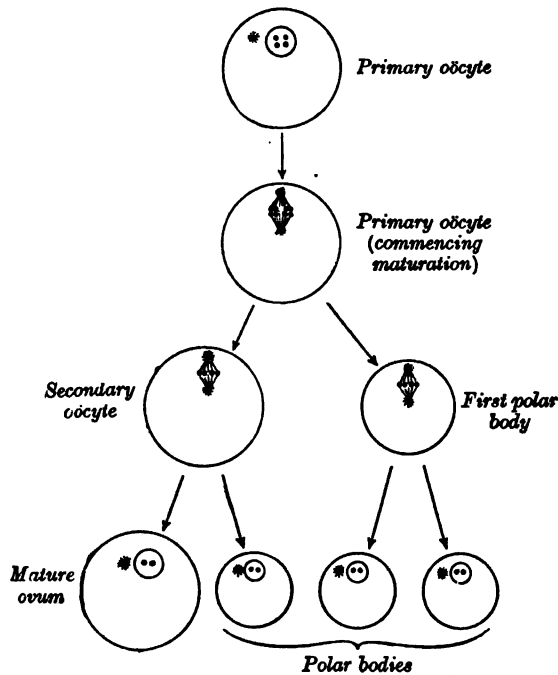

FIG. 63.—Diagram showing the reduction in number of the chromosomes in the process of maturation of the ovum.

This second division is also unequal, producing a large cell which constitutes the **mature ovum**, and a small cell, the **second polar body**. The first polar body frequently divides while the second is being formed, and as a final result four cells are produced, viz., the mature ovum and three polar bodies, each of which contains two chromosomes, *i. e.*, one-half the number present in the nuclei of the somatic cells of members of the same species. The nucleus of the mature ovum is termed the **female pronucleus**.

THE SPERMATOZOÖN.

The **spermatozoa** or **male germ cells** are developed in the testes and are present in enormous numbers in the seminal fluid. Each consists of a small but greatly modified cell. The human spermatozoön possesses a **head**, a **neck**, a **connecting piece** or **body**, and a **tail** (Fig. 64).

The **head** is oval or elliptical, but flattened, so that when viewed in profile it is pear-shaped. Its anterior two-thirds are covered by a layer of modified proto-

plasm, which is named the **head-cap**. This, in some animals, *e. g.*, the salamander, is prolonged into a barbed spear-like process or **perforator**, which probably facilitates the entrance of the spermatozoön into the ovum. The posterior part of the head exhibits an affinity for certain reagents, and presents a transversely striated appearance, being crossed by three or four dark bands. In some animals a central rod-like filament extends forward for about two-thirds of the length of the head, while in others a rounded body is seen near its centre. The head contains a mass of chromatin, and is generally regarded as the nucleus of the cell surrounded by a thin envelope.

FIG. 64.—Human spermatozoön. Diagrammatic. A. Surface view. B. Profile view. In C the head, neck, and connecting piece are more highly magnified.

The **neck** is less constricted in the human spermatozoön than in those of some of the lower animals. The **anterior centriole**, represented by two or three rounded particles, is situated at the junction of the head and neck, and behind it is a band of homogeneous substance.

The **connecting piece** or **body** is rod-like, and is limited behind by a **terminal disk**. The **posterior centriole** is placed at the junction of the body and neck and, like the anterior, consists of two or three rounded particles. From this centriole an **axial filament**, surrounded by a sheath, runs backward through the body and tail. In the body the sheath of the axial filament is encircled by a **spiral thread**, around which is an envelope containing mitochondria granules, and termed the **mitochondria sheath**.

The tail is of great length, and consists of the axial thread or filament, surrounded by its sheath, which may contain a spiral thread or may present a striated appearance. The terminal portion or **end-piece** of the tail consists of the axial filament only.

Krause gives the length of the human spermatozoön as between 52μ and 62μ , the head measuring 4 to 5μ , the connecting piece 6μ , and the tail from 41μ to 52μ .

By virtue of their tails, which act as propellers, the spermatozoa are capable of free movement, and if placed in favorable surroundings, *e. g.*, in the female passages, will retain their vitality and power of fertilizing for several days. In certain animals, *e. g.*, bats, it has been proved that spermatozoa retained in the female passages for several months are capable of fertilizing.

FIG. 65.—Scheme showing analogies in the process of maturation of the ovum and the development of the spermatids (young spermatozoa).

The spermatozoa are developed from the primitive germ cells which have become imbedded in the testes, and the stages of their development are very similar to those of the maturation of the ovum. The primary germ cells undergo division and produce a number of cells termed **spermatogonia**, and from these the **primary spermatocytes** are derived. Each primary spermatocyte divides into two **secondary spermatocytes**, and each secondary spermatocyte into two **spermatids** or young spermatozoa; from this it will be seen that a primary spermatocyte gives rise to four spermatozoa. On comparing this process with that of the maturation of the ovum (Fig. 65) it will be observed that the primary spermatocyte gives rise to two cells, the secondary spermatocytes, and the primary oöcyte to two cells, the secondary oöcyte and the first polar body. Again, the two secondary spermatocytes by their subdivision give origin to four spermatozoa, and the secondary oöcyte and first polar body to four cells, the mature ovum and three polar bodies. In the development of the spermatozoa, as in the maturation of the ovum, there is a reduction of the nuclear chromosomes to one-half of those present in the primary spermatocyte. But here the similarity ends, for it must be noted that the four spermatozoa are of equal size, and each is capable of fertilizing a mature ovum, whereas the three polar bodies are not only very much smaller than the mature ovum but are incapable of further development, and may be regarded as abortive ova.

FERTILIZATION OF THE OVUM.

Fertilization consists in the union of the spermatozoön with the mature ovum (Fig. 66). Nothing is known regarding the fertilization of the human ovum, but

the various stages of the process have been studied in other mammals, and from the knowledge so obtained it is believed that fertilization of the human ovum takes place in the lateral or ampullary part of the uterine tube, and the ovum is then conveyed along the tube to the cavity of the uterus—a journey probably occupying seven or eight days and during which the ovum loses its corona radiata and zona striata and undergoes segmentation. Sometimes the fertilized ovum is arrested in the uterine tube, and there undergoes development, giving rise to a *tubal pregnancy*; or it may fall into the abdominal cavity and produce an *abdominal pregnancy*. Occasionally the ovum is not expelled from the follicle when the latter ruptures, but is fertilized within the follicle and produces what is known as an *ovarian pregnancy*. Under normal conditions only one spermatozoön enters the

FIG. 66.—The process of fertilization in the ovum of a mouse. (After Sobotta.)

yolk and takes part in the process of fertilization. At the point where the spermatozoön is about to pierce, the yolk is drawn out into a conical elevation, termed the **cone of attraction**. As soon as the spermatozoön has entered the yolk, the peripheral portion of the latter is transformed into a membrane, the **vitelline membrane** which prevents the passage of additional spermatozoa. Occasionally a second spermatozoön may enter the yolk, thus giving rise to a condition of *polyspermy*: when this occurs the ovum usually develops in an abnormal manner and gives rise to a monstrosity. Having pierced the yolk, the spermatozoön loses its tail, while its head and connecting piece assume the form of a nucleus containing a cluster of chromosomes. This constitutes the **male pronucleus**, and associated with it there are a centriole and centrosome. The male pronucleus passes more deeply into the yolk, and coincidentally with this the granules of the cytoplasm surrounding it becomes radially arranged. The male and female pronuclei migrate toward each other, and,

meeting near the centre of the yolk, fuse to form a new nucleus, the **segmentation nucleus**, which therefore contains both male and female nuclear substance; the former transmits the individualities of the male ancestors, the latter those of the female ancestors, to the future embryo. By the union of the male and female pronuclei the number of chromosomes, is restored to that which is present in the nuclei of the somatic cells.

SEGMENTATION OF THE FERTILIZED OVUM.

The early segmentation of the human ovum has not yet been observed, but judging from what is known to occur in other mammals it may be regarded as certain that the process starts immediately after the ovum has been fertilized, *i. e.*, while the ovum is in the uterine tube. The segmentation nucleus exhibits the usual mitotic changes, and these are succeeded by a division of the ovum into two cells of nearly equal size.¹ The process is repeated again and again, so that the two cells are succeeded by four, eight, sixteen, thirty-two, and so on, with the result that a mass of cells is found within the zona striata, and to this mass the term

FIG. 67.—First stages of segmentation of a mammalian ovum. Semidiagrammatic. (From a drawing by Allen Thomson.) *s.p.* Zona striata. *p.p.* Polar bodies. *a.* Two-cell stage. *b.* Four-cell stage. *c.* Eight-cell stage. *d, e.* Morula stage.

morula is applied (Fig. 67). The segmentation of the mammalian ovum may not take place in the regular sequence of two, four, eight, etc., since one of the two first formed cells may subdivide more rapidly than the other, giving rise to a three- or a five-cell stage. The cells of the morula are at first closely aggregated, but soon they become arranged into an outer or peripheral layer, the **trophoblast**, which does not contribute to the formation of the embryo proper, and an **inner cell-mass**, from which the embryo is developed. Fluid collects between the trophoblast and the greater part of the inner cell-mass, and thus the morula is converted into

¹ In the mammalian ova the nutritive yolk or deutoplasm is small in amount and uniformly distributed throughout the cytoplasm; such ova undergo *complete* division during the process of segmentation, and are therefore termed *holoblastic*. In the ova of birds, reptiles, and fishes where the nutritive yolk forms by far the larger portion of the egg, the cleavage is limited to the formative yolk, and is therefore only *partial*, such ova are termed *meroblastic*. Again, it has been observed, in some of the lower animals, that the pronuclei do not fuse but merely lie in apposition. At the commencement of the segmentation process the chromosomes of the two pronuclei group themselves around the equator of the nuclear spindle and then divide; an equal number of male and female chromosomes travel to the opposite poles of the spindle, and thus the male and female pronuclei subscribe equal shares of chromatin to the nuclei of the two cells which result from the subdivision of the fertilized ovum.

a vesicle, the **blastodermic vesicle** (Fig. 68). The inner cell-mass remains in contact, however, with the trophoblast at one pole of the ovum; this is named the **embryonic pole**, since it indicates the situation where the future embryo will be developed. The cells of the trophoblast become differentiated into two strata: an outer, termed the **syncytium** or **syncytiotrophoblast**, so named because it consists of a layer of protoplasm studded with nuclei, but showing no evidence of subdivision into cells; and an inner layer, the **cytotrophoblast** or **layer of Langhans**, in which

Inner cell-mass

FIG. 68.—Blastodermic vesicle of *Vespertilio murinus*. (After van Beneden.)

FIG. 69.—Section through embryonic disk of *Vespertilio murinus*. (After van Beneden.)

FIG. 70.—Section through embryonic area of *Vespertilio murinus* to show the formation of the amniotic cavity. (After van Beneden.)

the cell outlines are defined. As already stated, the cells of the trophoblast do not contribute to the formation of the embryo proper; they form the ectoderm of the chorion and play an important part in the development of the placenta. On the deep surface of the inner cell-mass a layer of flattened cells, the **entoderm**, is differentiated and quickly assumes the form of a small sac, the **yolk-sac**. Spaces appear between the remaining cells of the mass (Fig. 69), and by the enlargement and coalescence of these spaces a cavity, termed the **amniotic cavity** (Fig. 70), is gradually

developed. The floor of this cavity is formed by the **embryonic disk** composed of a layer of prismatic cells, the **embryonic ectoderm**, derived from the inner cell-mass and lying in apposition with the entoderm.

The Primitive Streak; Formation of the Mesoderm.—The embryonic disk becomes oval and then pear-shaped, the wider end being directed forward. Near the narrow, posterior end an opaque streak, the **primitive streak** (Figs. 71 and 72), makes its appearance and extends along the middle of the disk for about one-half of its length; at the anterior end of the streak there is a knob-like thickening termed **Hensen's knot**. A shallow groove, the **primitive groove**, appears on the surface of the streak, and the anterior end of this groove communicates by means of an aperture, the **blastopore**, with the yolk-sac. The primitive streak is produced by a thickening of the axial part of the ectoderm, the cells of which multiply, grow downward, and blend with those of the subjacent entoderm (Fig. 73). From the sides of the primitive streak a third layer of cells, the **mesoderm**, extends lateralward between the ectoderm and entoderm; the caudal end of the primitive streak forms the cloacal membrane.

The extension of the mesoderm takes place throughout the whole of the embryonic and extra-embryonic areas of the ovum, except in certain regions. One of these is seen immediately in front of the neural tube. Here the mesoderm extends forward in the form of two crescentic masses, which meet in the middle line so as

FIG. 71.—Surface view of embryo of a rabbit. (After Kölliker.) *arg.* Embryonic disk. *pr.* Primitive streak.

FIG. 72.—Surface view of embryo of *Hylobates concolor*. (After Selenka.) The amnion has been opened to expose the embryonic disk.

to enclose behind them an area which is devoid of mesoderm. Over this area the ectoderm and entoderm come into direct contact with each other and constitute a thin membrane, the **buccopharyngeal membrane**, which forms a septum between the primitive mouth and pharynx. In front of the buccopharyngeal area, where the lateral crescents of mesoderm fuse in the middle line, the pericardium is

afterward developed, and this region is therefore designated the **pericardial area**. A second region where the mesoderm is absent, at least for a time, is that immediately in front of the pericardial area. This is termed the **proamniotic area**, and is the region where the **proamnion** is developed; in man, however, a proamnion is apparently never formed. A third region is at the hind end of the embryo where the ectoderm and entoderm come into apposition and form the **cloacal membrane**.

FIG. 73.—Series of transverse sections through the embryonic disk of *Tarsius*. (After Hubrecht.) Section I passes through the disk, in front of Hansen's knot and shows only the ectoderm and entoderm. Sections II, III, and IV pass through Hansen's knot, which is seen in V tapering away into the primitive streak. In III, IV, and V the mesoderm is seen springing from the keel-like thickening of the ectoderm, which in III and IV is observed to be continuous into the entoderm.

The blastoderm now consists of three layers, named from without inward: ectoderm, mesoderm, and entoderm; each has distinctive characteristics and gives rise to certain tissues of the body.¹

Ectoderm.—The ectoderm consists of columnar cells, which are, however, somewhat flattened or cubical toward the margin of the embryonic disk. It forms the whole of the nervous system, the epidermis of the skin, the lining cells of the sebaceous, sudoriferous, and mammary glands, the hairs and nails, the epithelium of the nose and adjacent air sinuses, and that of the cheeks and roof of the mouth. From it also are derived the enamel of the teeth, and the anterior lobe of the hypophysis cerebri, the epithelium of the cornea, conjunctiva, and lacrimal glands, and the neuro-epithelium of the sense organs.

Entoderm.—The entoderm consists at first of flattened cells, which subsequently become columnar. It forms the epithelial lining of the whole of the digestive tube excepting part of the mouth and pharynx and the terminal part of the rectum

¹ The mode of formation of the germ layers in the human ovum has not yet been observed; in the youngest known human ovum (viz., that described by Bryce and Teacher), all three layers are already present and the mesoderm is split into its two layers. The extra-embryonic coelom is of considerable size, and scattered mesodermal strands are seen stretching between the mesoderm of the yolk-sac and that of the chorion.

(which are lined by involutions of the ectoderm), the lining cells of all the glands which open into the digestive tube, including those of the liver and pancreas, the epithelium of the auditory tube and tympanic cavity, of the trachea, bronchi, and air cells of the lungs, of the urinary bladder and part of the urethra, and that which lines the follicles of the thyroid gland and thymus.

Mesoderm.—The mesoderm consists of loosely arranged branched cells surrounded by a considerable amount of intercellular fluid. From it the remaining tissues of the body are developed. The endothelial lining of the heart and blood-vessels and the blood corpuscles are, however, regarded by some as being of entodermal origin.

FIG. 74.—A series of transverse sections through an embryo of the dog. (After Bonnet.) Section I is the most anterior. In V the neural plate is spread out nearly flat. The series shows the uprising of the neural folds to form the neural canal. *a.* Aorta. *c.* Intermediate cell mass. *ect.* Ectoderm. *ent.* Entoderm. *A, A.* Rudiments of endothelial heart tubes. In III, IV, and V the scattered cells represented between the ectoderm and splanchnic layer of mesoderm are the vasoformative cells which give origin in front, according to Bonnet, to the heart tubes. *l.p.* Lateral plate still undivided in I, II, and III; in IV and V split into somatic (*sm*) and splanchnic (*sp*) layers of mesoderm. *mes.* Mesoderm. *p.* Pericardium. *so.* Primitive segment.

As the mesoderm develops between the ectoderm and entoderm it is separated into lateral halves by the neural tube and notochord, presently to be described. A longitudinal groove appears on the dorsal surface of either half and divides it into a medial column, the **paraxial mesoderm**, lying on the side of the neural tube, and a lateral portion, the **lateral mesoderm**. The mesoderm in the floor of the groove connects the paraxial with the lateral mesoderm and is known as the **intermediate cell-mass**; in it the genito-urinary organs are developed. The lateral mesoderm splits into two layers, an outer or **somatic**, which becomes applied to the inner surface of the ectoderm, and with it forms the **somatopleure**; and an inner or **splanchnic**, which adheres to the entoderm, and with it forms the **splanchnopleure** (Fig. 74). The space between the two layers of the lateral mesoderm is termed the **coelom**.

THE NEURAL GROOVE AND TUBE.

In front of the primitive streak two longitudinal ridges, caused by a folding up of the ectoderm, make their appearance, one on either side of the middle line (Fig. 74). These are named the **neural folds**; they commence some little distance behind the anterior end of the embryonic disk, where they are continuous with each other, and from there gradually extend backward, one on either side of the anterior end of the primitive streak. Between these folds is a shallow median groove, the **neural groove** (Figs. 74, 75). The groove gradually deepens as the neural folds become elevated, and ultimately the folds meet and coalesce in the middle line and convert the groove into a closed tube, the **neural tube or canal** (Fig. 76), the ectodermal wall of which forms the rudiment of the nervous system. By the coalescence of the neural folds over the anterior end of the primitive streak, the blastopore no longer opens on the surface but into the closed canal of the neural

tube, and thus a transitory communication, the **neurenteric canal**, is established between the neural tube and the primitive digestive tube. The coalescence of the neural folds occurs first in the region of the hind-brain, and from there extends forward and backward; toward the end of the third week the front opening (anterior neuropore) of the tube finally closes at the anterior end of the future brain, and forms a recess which is in contact, for a time, with the overlying ectoderm; the hinder part of the neural groove presents for a time a rhomboidal shape, and to this expanded portion the term **sinus rhomboidalis** has been applied (Fig. 76). Before the neural groove is closed a ridge of ectodermal cells appears along the prominent margin of each neural fold; this is termed the **neural crest** or **ganglion ridge**, and from it the spinal and cerebral nerve ganglia and the ganglia of the sympathetic nervous system are developed. By the upward growth of the mesoderm the neural tube is ultimately separated from the overlying ectoderm.

The cephalic end of the neural groove exhibits several dilatations, which, when the tube is closed, assume the form of three vesicles; these constitute the three **primary cerebral vesicles**, and correspond respectively to the future **prosencephalon**

(fore-brain), **mesencephalon** (mid-brain), and **rhombencephalon** (hind-brain) (Fig. 76). The walls of the vesicles are developed into the nervous tissue and neuroglia of the brain, and their cavities are modified to form its ventricles. The remainder of the tube forms the **medulla spinalis** or **spinal cord**; from its ectodermal wall the nervous and neuroglial elements of the medulla spinalis are developed while the cavity persists as the central canal.

THE NOTOCHORD.

The notochord (Fig. 77) consists of a rod of cells situated on the ventral aspect of the neural tube; it constitutes the foundation of the axial skeleton, since around it the segments of the vertebral column are formed. Its appearance synchronizes

with that of the neural tube. On the ventral aspect of the neural groove an axial thickening of the entoderm takes place; this thickening assumes the appearance of a furrow—the **chordal furrow**—the margins of which come into contact, and so convert it into a solid rod of cells—the **notochord**—which is then separated from the entoderm. It extends throughout the entire length of the future vertebral

FIG. 77.—Transverse section of a chick embryo of forty-five hours' incubation. (Balfour.)

column, and reaches as far as the anterior end of the mid-brain, where it ends in a hook-like extremity in the region of the future dorsum sellae of the sphenoid bone. It lies at first between the neural tube and the entoderm of the yolk-sac, but soon becomes separated from them by the mesoderm, which grows medialward and surrounds it. From the mesoderm surrounding the neural tube and notochord, the skull and vertebral column, and the membranes of the brain and medulla spinalis are developed.

THE PRIMITIVE SEGMENTS.

Toward the end of the second week transverse segmentation of the paraxial mesoderm begins, and it is converted into a series of well-defined, more or less cubical masses, the **primitive segments** (Figs. 76, 77, 78), which occupy the entire length of the trunk on either side of the middle line from the occipital region of the head. Each segment contains a central cavity—**myocoel**—which, however, is soon filled with angular and spindle-shaped cells.

The primitive segments lie immediately under the ectoderm on the lateral aspect of the neural tube and notochord, and are connected to the lateral mesoderm by the **intermediate cell-mass**. Those of the trunk may be arranged in the following groups, viz.: cervical 8, thoracic 12, lumbar 5, sacral 5, and coccygeal from 5 to 8. Those of the occipital region of the head are usually described as being four in number. In mammals primitive segments of the head can only be recognized in the occipital region, but a study of the lower vertebrates leads to the belief that they are present also in the anterior part of the head, and that altogether nine segments are represented in the cephalic region.

FIG. 78.—Dorsum of human embryo, 2.11 mm. in length (After Eternod.)

SEPARATION OF THE EMBRYO.

The embryo increases rapidly in size, but the circumference of the embryonic disk, or line of meeting of the embryonic and amniotic parts of the ectoderm, is of relatively slow growth and gradually comes to form a constriction between the embryo and the greater part of the yolk-sac. By means of this constriction, which corresponds to the future umbilicus, a small part of the yolk-sac is enclosed within the embryo and constitutes the primitive digestive tube.

The embryo increases more rapidly in length than in width, and its cephalic and caudal ends soon extend beyond the corresponding parts of the circumference of the embryonic disk and are bent in a ventral direction to form the **cephalic** and **caudal folds** respectively (Figs. 84 and 85). The cephalic fold is first formed, and

FIG. 79.—Section through the embryo which is represented in Fig. 75. (After Graf Spee.)

as the proamniotic area (page 87) lying immediately in front of the pericardial area (page 87) forms the anterior limit of the circumference of the embryonic disk, the forward growth of the head necessarily carries with it the posterior end of the pericardial area, so that this area and the buccopharyngeal membrane are folded back under the head of the embryo which now encloses a diverticulum of the yolk-sac named the **fore-gut**. The caudal end of the embryo is at first connected to the chorion by a band of mesoderm called the **body-stalk**, but with the formation of the caudal fold the body-stalk assumes a ventral position; a diverticulum of the yolk-sac extends into the tail fold and is termed the **hind-gut**. Between the fore-gut and the hind-gut there exists for a time a wide opening into the yolk-sac, but the latter is gradually reduced to a small pear-shaped sac (sometimes termed the **umbilical vesicle**), and the channel of communication is at the same time narrowed and elongated to form a tube called the **vitelline duct**.

THE YOLK-SAC.

The yolk-sac (Figs. 79 and 80) is situated on the ventral aspect of the embryo; it is lined by entoderm, outside of which is a layer of mesoderm. It is filled with fluid, the **vitelline fluid**, which possibly may be utilized for the nourishment of the embryo during the earlier stages of its existence. Blood is conveyed to the wall of the sac by the primitive aortæ, and after circulating through a wide-meshed capillary plexus, is returned by the vitelline veins to the tubular heart of the embryo. This constitutes the **vitelline circulation**, and by means of it nutritive material is absorbed from the yolk-sac and conveyed to the embryo. At the end of the fourth week the yolk-sac presents the appearance of a small pear-shaped vesicle (umbilical vesicle) opening into the digestive tube by a long narrow tube, the **vitelline duct**. The vesicle can be seen in the after-birth as a small, somewhat oval-shaped body whose diameter varies from 1 mm. to 5 mm.; it is situated between the amnion and the chorion and may lie on or at a varying distance from the placenta. As a rule the duct undergoes complete obliteration during the seventh week, but in about three per cent. of cases its proximal part persists as a diverticulum from the small intestine, **Meckel's diverticulum**, which is situated about three or four feet above the ileocolic junction, and may be attached by a fibrous cord to the abdominal wall at the umbilicus. Sometimes a narrowing of the lumen of the ileum is seen opposite the site of attachment of the duct.

FIG. 80.—Human embryo from thirty-one to thirty-four days. (Hia.)

DEVELOPMENT OF THE FETAL MEMBRANES AND THE PLACENTA.

The Allantois (Figs. 82 to 85).—The allantois arises as a tubular diverticulum of the posterior part of the yolk-sac; when the hind-gut is developed the allantois is carried backward with it and then opens into the cloaca or terminal part of the hind-gut: it grows out into the body-stalk, a mass of mesoderm which lies below and around the tail end of the embryo. The diverticulum is lined by entoderm and covered by mesoderm, and in the latter are carried the allantoic or umbilical vessels.

In reptiles, birds, and many mammals the allantois becomes expanded into a vesicle which projects into the extra-embryonic cœlom. If its further development be traced in the bird, it is seen to project to the right side of the embryo, and, gradually expanding, it spreads over its dorsal surface as a flattened sac between the amnion and the serosa, and extending in all directions, ultimately surrounds the yolk. Its outer wall becomes applied to and fuses with the serosa, which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by the two allantoic or umbilical arteries, which are continuous with the primitive aortæ, and after circulating through the allantoic capillaries, is returned to the primitive heart by the two umbilical veins. In this way the allantoic circulation, which is of the utmost importance in connection with the respiration and nutrition

of the chick, is established. Oxygen is taken from, and carbonic acid is given up to the atmosphere through the egg-shell, while nutritive materials are at the same time absorbed by the blood from the yolk.

FIG. 81.—Diagram showing earliest observed stage of human ovum.

FIG. 82.—Diagram illustrating early formation of allantois and differentiation of body-stalk.

In man and other primates the nature of the allantois is entirely different from that just described. Here it exists merely as a narrow, tubular diverticulum of the hind-gut, and never assumes the form of a vesicle outside the embryo. With the formation of the amnion the embryo is, in most animals, entirely separated from the chorion, and is only again united to it when the allantoic mesoderm spreads over and becomes applied to its inner surface. The human embryo, on the other hand, as was pointed out by His, is never wholly separated from the chorion, its tail end being from the first connected with the chorion by means of a thick band of mesoderm, named the **body-stalk** (*Bauchstiel*); into this stalk the tube of the allantois extends (Fig. 79).

FIG. 83.—Diagram showing later stage of allantoic development with commencing constriction of the yolk-sac.

FIG. 84.—Diagram showing the expansion of amnion and delimitation of the umbilicus.

The Amnion.—The amnion is a membranous sac which surrounds and protects the embryo. It is developed in reptiles, birds, and mammals, which are hence called "Amniota;" but not in amphibia and fishes, which are consequently termed "Anamnia."

In the human embryo the earliest stages of the formation of the amnion have not been observed; in the youngest embryo which has been studied the amnion was already present as a closed sac (Figs. 81 and 88), and, as indicated on page 85,

appears in the inner cell-mass as a cavity. This cavity is roofed in by a single stratum of flattened, ectodermal cells, the *amniotic ectoderm*, and its floor consists of the prismatic ectoderm of the embryonic disk—the continuity between the roof and floor being established at the margin of the embryonic disk. Outside the amniotic ectoderm is a thin layer of mesoderm, which is continuous with that of the somatopleure and is connected by the body-stalk with the mesodermal lining of the chorion.

When first formed the amnion is in contact with the body of the embryo, but about the fourth or fifth week fluid (*liquor amnii*) begins to accumulate within it. This fluid increases in quantity and causes the amnion to expand and ultimately to adhere to the inner surface of the chorion, so that the extra-embryonic part of the coelom is obliterated. The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, after which it diminishes somewhat; at the end of pregnancy it amounts to about 1 litre. It allows of the free movements of the fetus during the later stages of pregnancy, and also protects it by diminishing the risk of injury from without. It contains less than 2 per cent. of solids, consisting of

urea and other extractives, inorganic salts, a small amount of protein, and frequently a trace of sugar. That some of the liquor amnii is swallowed by the fetus is proved by the fact that epidermal debris and hairs have been found among the contents of the fetal alimentary canal.

In reptiles, birds, and many mammals the amnion is developed in the following manner: At the point of constriction where the primitive digestive tube of the embryo joins the yolk-sac a reflection of folding upward of the somatopleure takes place. This, the **amniotic fold** (Fig. 86), first makes its appearance at the cephalic extremity, and subsequently at the caudal end and sides of the embryo, and gradually rising more and more, its different parts meet and fuse over the dorsal aspect of the embryo, and enclose a cavity, the **amniotic cavity**. After the fusion of the edges of the amniotic fold, the two layers of the fold become completely separated, the inner forming the **amnion**, the outer the **false amnion** or **serosa**. The space between the amnion and the serosa constitutes the extra-embryonic coelom, and for a time communicates with the embryonic coelom.

FIG. 87.—Model of human embryo 1.3 mm. long. (After Eternod)

The Umbilical Cord and Body-stalk.—The umbilical cord (Fig. 85) attaches the fetus to the placenta; its length at full time, as a rule, is about equal to the length of the fetus, *i. e.*, about 50 cm., but it may be greatly diminished or increased. The rudiment of the umbilical cord is represented by the tissue which connects the rapidly growing embryo with the extra-embryonic area of the ovum. Included in this tissue are the body-stalk and the vitelline duct—the former containing the allantoic diverticulum and the umbilical vessels, the latter forming the communication between the digestive tube and the yolk-sac. The body-stalk is the posterior segment of the embryonic area, and is attached to the chorion. It consists of a plate of mesoderm covered by thickened ectoderm on which a trace of the neural groove can be seen, indicating its continuity with the embryo. Running through its mesoderm are the two umbilical arteries and the two umbilical veins, together with the canal of the allantois—the last being lined by entoderm (Fig. 87). Its dorsal surface is covered by the amnion, while its ventral surface is bounded by the extra-embryonic coelom, and is in contact with the vitelline duct and yolk-sac. With the rapid elongation of the embryo and the formation of the tail fold, the body stalk comes to lie on the ventral surface of the embryo (Figs. 84 and 85), where its mesoderm blends with that of the yolk-sac and the vitelline duct. The lateral leaves of somatopleure then grow round on each side, and, meeting on the ventral

aspect of the allantois, enclose the vitelline duct and vessels, together with a part of the extra-embryonic coelom; the latter is ultimately obliterated. The cord is covered by a layer of ectoderm which is continuous with that of the amnion, and its various constituents are enveloped by embryonic gelatinous tissue, **jelly of Wharton**. The vitelline vessels and duct, together with the right umbilical vein, undergo atrophy and disappear; and thus the cord, at birth, contains a pair of umbilical arteries and one (the left) umbilical vein.

Implantation or Imbedding of the Ovum.—As described (page 82), fertilization of the ovum occurs in the lateral or ampullary end of the uterine tube and is immediately followed by segmentation. On reaching the cavity of the uterus the segmented ovum adheres like a parasite to the uterine mucous membrane, destroys the epithelium over the area of contact, and excavates for itself a cavity in the mucous membrane in which it becomes imbedded. In the ovum described by Bryce and Teacher¹ the point of entrance was visible as a small gap closed by a mass of fibrin and leucocytes; in the ovum described by Peters² the opening was covered by a mushroom-shaped mass of fibrin and blood-clot (Fig. 88), the narrow stalk of which plugged the aperture in the mucous membrane. Soon, however, all trace of the opening is lost and the ovum is then completely surrounded by the uterine mucous membrane.

The structure actively concerned in the process of excavation is the trophoblast of the ovum, which possesses the power of dissolving and absorbing the uterine

¹ Contribution to the study of the early development and imbedding of the human ovum, 1908.

² Die Einbettung des menschlichen Eies, 1899.

tissues. The trophoblast proliferates rapidly and forms a network of branching processes which cover the entire ovum and invade and destroy the maternal tissues and open into the maternal bloodvessels, with the result that the spaces in the trophoblastic network are filled with maternal blood; these spaces communicate freely with one another and become greatly distended and form the intervillous space.

The Decidua.—Before the fertilized ovum reaches the uterus, the mucous membrane of the body of the uterus undergoes important changes and is then

known as the **decidua**. The thickness and vascularity of the mucous membrane are greatly increased; its glands are elongated and open on its free surface by funnel-shaped orifices, while their deeper portions are tortuous and dilated into irregular spaces. The interglandular tissue is also increased in quantity, and is crowded with large round, oval, or polygonal cells, termed **decidual cells**. These changes are well advanced by the second month of pregnancy, when the mucous membrane consists of the following strata (Fig. 89): (1) **stratum compactum**, next the free surface; in this the uterine glands are only slightly expanded, and are lined by columnar cells; (2) **stratum spongiosum**, in which the gland tubes are greatly dilated and very tortuous, and are ultimately separated from one another by only a small amount of interglandular tissue, while their lining cells are flattened or cubical; (3) a thin **unaltered or boundary layer**, next the uterine muscular fibres, containing the deepest parts of the uterine glands, which are not dilated, and are lined with columnar epithelium; it is from this epithelium that the epithelial lining of the uterus is regenerated after pregnancy. Distinctive names are applied to different portions of the decidua. The part which covers in the ovum is named the **decidua capsularis**; the portion which intervenes between the ovum and the uterine wall is named the **decidua basalis** or **decidua placentalis**; it is here that the placenta is subsequently

developed. The part of the decidua which lines the remainder of the body of the uterus is known as the **decidua vera** or **decidua parietalis**.

Coincidentally with the growth of the embryo, the decidua capsularis is thinned and extended (Fig. 90) and the space between it and the decidua vera is gradually obliterated, so that by the third month of pregnancy the two are in contact. By

the fifth month of pregnancy the decidua capsularis has practically disappeared, while during the succeeding months the decidua vera also undergoes atrophy, owing to the increased pressure. The glands of the stratum compactum are obliterated, and their epithelium is lost. In the stratum spongiosum the glands are compressed and appear as slit-like fissures, while their epithelium undergoes degeneration. In the unaltered or boundary layer, however, the glandular epithelium retains a columnar or cubical form.

The Chorion (Figs. 80 to 85).—The chorion consists of two layers: an outer formed by the primitive ectoderm or trophoblast, and an inner by the somatic mesoderm; with this latter the amnion is in contact. The trophoblast is made up of an internal layer of cubical or prismatic cells, the **cytotrophoblast** or **layer of Langhans**, and an external layer of richly nucleated protoplasm devoid of cell boundaries, the **syncytiotrophoblast**. It undergoes rapid proliferation and forms numerous processes, the **chorionic villi**, which invade and destroy the uterine

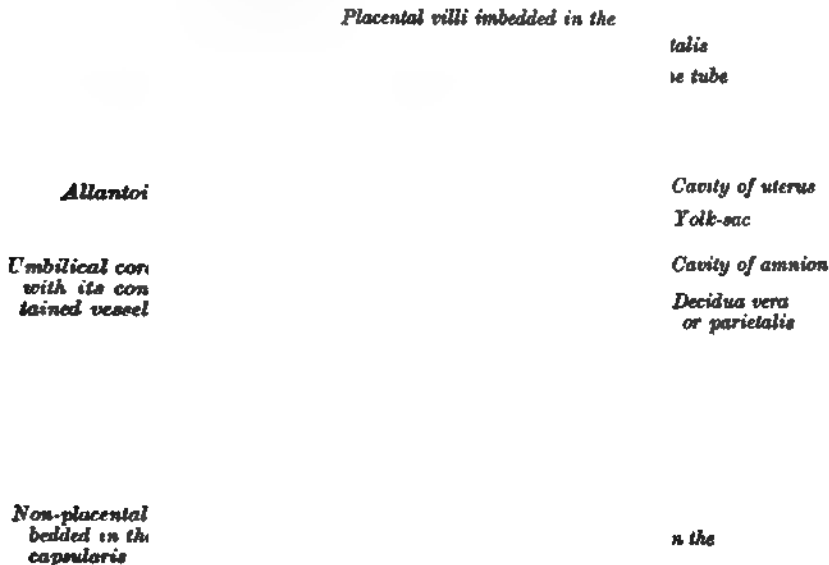

FIG. 90.—Sectional plan of the gravid uterus in the third and fourth month. (Modified from Wagner.)

decidua and at the same time absorb from it nutritive materials for the growth of the embryo. The chorionic villi are at first small and non-vascular, and consist of trophoblast only, but they increase in size and ramify, while the mesoderm, carrying branches of the umbilical vessels, grows into them, and in this way they are vascularized. Blood is carried to the villi by the branches of the umbilical arteries, and after circulating through the capillaries of the villi, is returned to the embryo by the umbilical veins. Until about the end of the second month of pregnancy the villi cover the entire chorion, and are almost uniform in size (Fig. 82), but after this they develop unequally. The greater part of the chorion is in contact with the decidua capsularis (Fig. 90), and over this portion the villi, with their contained vessels, undergo atrophy, so that by the fourth month scarcely a trace of them is left, and hence this part of the chorion becomes smooth, and is named the **chorion laeve**; as it takes no share in the formation of the placenta, it is also named the non-placental part of the chorion. On the other hand, the villi on that part of the chorion which is in contact with the decidua placentalis increase

greatly in size and complexity, and hence this part is named the **chorion frondosum** (Fig. 85).

The Placenta.—The placenta connects the fetus to the uterine wall, and is the organ by means of which the nutritive, respiratory, and excretory functions of the fetus are carried on. It is composed of **fetal** and **maternal** portions.

Fetal Portion.—The fetal portion of the placenta consists of the villi of the chorion frondosum; these branch repeatedly, and increase enormously in size.

These greatly ramified villi are suspended in the intervillous space, and are bathed in maternal blood, which is conveyed to the space by the uterine arteries and carried away by the uterine veins. A branch of an umbilical artery enters each villus and ends in a capillary plexus from which the blood is drained by a tributary of the umbilical vein. The vessels of the villus are surrounded by a thin layer of mesoderm consisting of gelatinous connective tissue, which is covered by two strata of ectodermal cells derived from the trophoblast: the deeper stratum, next the mesodermic tissue, represents the cytotrophoblast or layer of Langhans; the superficial, in contact

with the maternal blood, the syncytiotrophoblast (Figs. 91 and 92). After the fifth month the two strata of cells are replaced by a single layer of somewhat flattened cells.

fib *ca* *vs*

FIG. 92.—Diagram to illustrate the second phase of the placenta. (After Peters.) The mesodermic core has now invaded the strands of the trophoblast, and is beginning to branch. *ca.* Maternal capillary. *core.* Core of villus. *fib.* Fibrinous material deposited at junction of trophoblast with decidua. *mcp.* Endothelium of maternal capillary. *mes.* Mesoderm. *sy.* Syncytiotrophoblast. *vs.* Intervillous space.

Maternal Portion.—The maternal portion of the placenta is formed by the decidua placentalis containing the intervillous space. As already explained, this space is produced by the enlargement and intercommunication of the spaces in the trophoblastic network. The changes involve the disappearance of the greater portion of the stratum compactum, but the deeper part of this layer persists and is condensed to form what is known as the **basal plate**. Between this plate and the uterine muscular fibres are the stratum spongiosum and the boundary layer;

through these and the basal plate the uterine arteries and veins pass to and from the intervillous space. The endothelial lining of the uterine vessels ceases at the point where they terminate in the intervillous space which is lined by the syncytiotrophoblast. Portions of the stratum compactum persist and are condensed to form a series of septa, which extend from the basal plate through the thickness of the placenta and subdivide it into the lobules or **cotyledons** seen on the uterine surface of the detached placenta.

The fetal and maternal blood currents traverse the placenta, the former passing through the bloodvessels of the placental villi and the latter through the intervillous space (Fig. 93). The two currents do not intermingle, being separated from each other by the delicate walls of the villi. Nevertheless, the fetal blood is able to absorb, through the walls of the villi, oxygen and nutritive materials from the maternal blood, and give up to the latter its waste products. The blood, so purified, is carried back to the fetus by the umbilical vein. It will thus be seen that the placenta not only establishes a mechanical connection between the mother and the fetus, but subserves for the latter the purposes of nutrition, respiration, and excretion. In favor of the view that the placenta possesses certain selective powers may be mentioned the fact that glucose is more plentiful in the maternal than in the fetal blood. It is interesting to note also that the proportion of iron, and of lime and potash, in the fetus is increased during the last months of pregnancy. Further, there is evidence that the maternal leucocytes may migrate into the fetal blood, since leucocytes are much more numerous in the blood of the umbilical vein than in that of the umbilical arteries.

The placenta is usually attached near the fundus uteri, and more frequently on the posterior than on the anterior wall of the uterus. It may, however, occupy a lower position and, in rare cases, its site is close to the orificium internum uteri, which it may occlude, thus giving rise to the condition known as *placenta praevia*.

Separation of the Placenta.—After the child is born, the placenta and membranes are expelled from the uterus as the *after-birth*. The separation of the placenta from the uterine wall takes place through the stratum spongiosum, and necessarily causes rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction of the uterine muscular fibres, and thus *postpartum hemorrhage* is controlled. The epithelial lining of the uterus is regenerated by the proliferation and extension of the epithelium which lines the persistent portions of the uterine glands in the unaltered layer of the decidua.

The expelled placenta appears as a discoid mass which weighs about 450 gm. and has a diameter of from 15 to 20 cm. Its average thickness is about 3 cm., but this diminishes rapidly toward the circumference of the disk, which is continuous with the membranes. Its uterine surface is divided by a series of fissures into lobules or **cotyledons**, the fissures containing the remains of the septa which extended

Amnion Umbilical
 Chorion artery Umbilical

Uterine vein Uterine artery

FIG. 93.—Scheme of placental circulation.

between the maternal and fetal portions. Most of these septa end in irregular or pointed processes; others, especially those near the edge of the placenta, pass through its thickness and are attached to the chorion. In the early months these septa convey branches of the uterine arteries which open into the intervillous space on the surfaces of the septa. The fetal surface of the placenta is smooth, being closely invested by the amnion. Seen through the latter, the chorion presents a mottled appearance, consisting of gray, purple, or yellowish areas. The umbilical cord is usually attached near the centre of the placenta, but may be inserted anywhere between the centre and the margin; in some cases it is inserted into the membranes, *i. e.*, the **velamentous insertion**. From the attachment of the cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper and larger than the arteries. The remains of the vitelline duct and yolk-sac may be sometimes observed beneath the amnion, close to the cord, the former as an attenuated thread, the latter as a minute sac.

On section, the placenta presents a soft, spongy appearance, caused by the greatly branched villi; surrounding them is a varying amount of maternal blood giving the dark red color to the placenta. Many of the larger villi extend from the chorionic to the decidual surface, while others are attached to the septa which separate the cotyledons; but the great majority of the villi hang free in the intervillous space.

The further growth of the embryo will be best understood from a description of the principal facts relating to the development of the chief systems of which the body consists.

DEVELOPMENT OF THE PARIETES.

The Skeleton.—The skeleton is of mesodermal origin, and may be divided into (a) that of the trunk (**axial skeleton**), comprising the vertebral column, skull, ribs, and sternum, and (b) that of the limbs (**appendicular skeleton**).

The Vertebral Column.—The notochord (Fig. 77) is a temporary structure and forms a central axis, around which the segments of the vertebral column are developed.¹ It is derived from the entoderm, and consists of a rod of cells, which lies on the ventral aspect of the neural tube and reaches from the anterior end of the mid-brain to the extremity of the tail. On either side of it is a column of paraxial mesoderm which becomes subdivided into a number of more or less cubical segments, the **primitive segments** (Figs. 77 and 78). These are separated from one another by **intersegmental septa** and are arranged symmetrically on either side of the neural tube and notochord: to every segment a spinal nerve is distributed. At first each segment contains a central cavity, the **myocoel**, but this is soon filled with a core of angular and spindle-shaped cells. The cells of the segment become differentiated into three groups, which form respectively the cutis-plate or dermatome, the muscle-plate or myotome, and the sclerotome (Fig. 94). The **cutis-plate** is placed on the lateral and dorsal aspect of the myocoel, and from it the true skin of the corresponding segment is derived; the **muscle-plate** is situated on the medial side of the cutis-plate and furnishes the muscles of the segment. The cells of the **sclerotome** are largely derived from those forming the core of the myocoel, and lie next the notochord. Fusion of the individual sclerotomes in an antero-posterior direction soon takes place, and thus a continuous strand of cells, the **sclerotogenous layer**, is formed along the ventro-lateral aspects of the neural tube. The cells of this layer proliferate rapidly, and extending medialward surround the notochord; at the same time they grow backward on the lateral aspects of the neural tube and eventually surround it, and thus the notochord and neural tube are enveloped

¹ In the amphioxus the notochord persists and forms the only representative of a skeleton in that animal.

by a continuous sheath of mesoderm, which is termed the **membranous vertebral column**. In this mesoderm the original segments are still distinguishable, but each is now differentiated into two portions, an anterior, consisting of loosely arranged cells, and a posterior, of more condensed tissue (Fig. 95, *A* and *B*). Between the two portions the rudiment of the intervertebral fibrocartilage is laid down (Fig. 95, *C*). Cells from the posterior mass grow into the intervals between the myotomes (Fig. 95, *B* and *C*) of the corresponding and succeeding segments, and extend both dorsally and ventrally; the dorsal extensions surround the neural tube and represent the future vertebral arch, while the ventral extend into the body-wall as the costal processes. The hinder part of the posterior mass joins the anterior mass of the succeeding segment to form the vertebral body. Each vertebral body is therefore a composite of two segments, being formed from the posterior portion of one segment and the anterior part of that immediately behind it. The vertebral

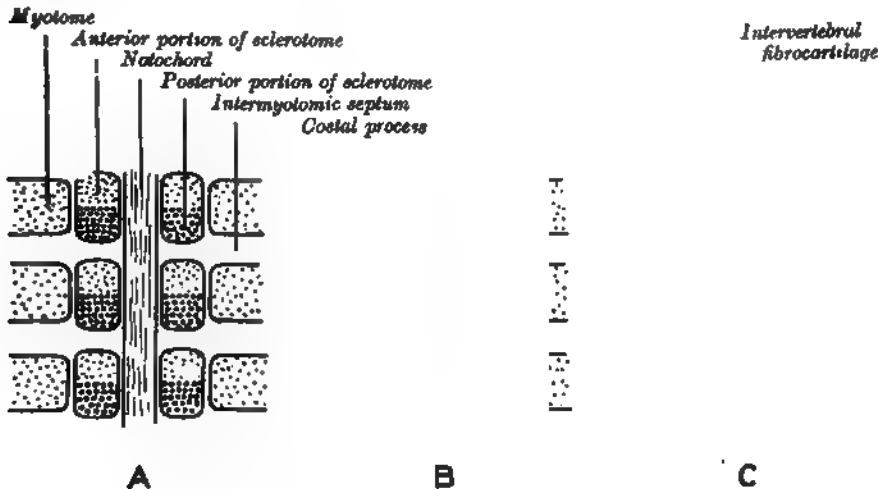

FIG. 95.—Scheme showing the manner in which each vertebral centrum is developed from portions of two adjacent segments.

and costal arches are derivatives of the posterior part of the segment in front of the intersegmental septum with which they are associated.

This stage is succeeded by that of the **cartilaginous vertebral column**. In the fourth week two cartilaginous centres make their appearance, one on either side of the notochord; these extend around the notochord and form the body of the cartilaginous vertebra. A second pair of cartilaginous foci appear in the lateral parts of the vertebral bow, and grow backward on either side of the neural tube to form the cartilaginous vertebral arch, and a separate cartilaginous centre appears for each costal process. By the eighth week the cartilaginous arch has fused with the body, and in the fourth month the two halves of the arch are joined on the dorsal aspect of the neural tube. The spinous process is developed from the junction of the two halves of the vertebral arch. The transverse process grows out from the vertebral arch behind the costal process.

In the upper cervical vertebræ a band of mesodermal tissue connects the ends of the vertebral arches across the ventral surfaces of the intervertebral fibrocartilages. This is termed the **hypochordal bar** or **brace**; in all except the first it is transitory and disappears by fusing with the fibrocartilages. In the atlas, however, the entire bow persists and undergoes chondrification; it develops into the anterior arch of the bone, while the cartilage representing the body of the atlas forms the dens or odontoid process which fuses with the body of the second cervical vertebra.

FIG. 96.—Sagittal section through an intervertebral fibrocartilage and adjacent parts of two vertebræ of an advanced sheep's embryo. (Kölliker.)

The portions of the notochord which are surrounded by the bodies of the vertebræ atrophy, and ultimately disappear, while those which lie in the centres of the intervertebral fibrocartilages undergo enlargement, and persist throughout life as the central **nucleus pulposus** of the fibrocartilages (Fig. 96).

The Ribs.—The ribs are formed from the ventral or costal processes of the primitive vertebral bows, the processes extending between the muscle-plates. In the *thoracic region* of the vertebral column the costal processes grow lateralward to form a series of arches, the **primitive costal arches**. As already described, the transverse process grows out behind the vertebral end of each arch. It is at first connected to the costal process by continuous mesoderm, but this becomes differentiated later to form the costotransverse ligament; between the costal process and the tip of the transverse process the costotransverse joint is formed by absorption. The costal process becomes separated from the vertebral bow by the development of the costocentral joint. In the *cervical vertebræ* (Fig. 97) the transverse process forms the posterior boundary of the foramen transversarium, while the costal process corresponding to the head and neck of the rib fuses with the

body of the vertebra, and forms the antero-lateral boundary of the foramen. The distal portions of the primitive costal arches remain undeveloped; occasionally the arch of the seventh cervical vertebra undergoes greater development, and by the formation of costovertebral joints is separated off as a rib. In the *lumbar region* the distal portions of the primitive costal arches fail; the proximal portions fuse with the transverse processes to form the transverse processes of descriptive anatomy. Occasionally a movable rib is developed in connection with the first lumbar vertebra. In the *sacral region* costal processes are developed only in connection with the upper three, or it may be four, vertebrae; the processes of adjacent segments fuse with one another to form the lateral parts of the sacrum. The *coccygeal vertebrae* are devoid of costal processes.

FIG. 97.—Diagrams showing the portions of the adult vertebrae derived respectively from the bodies, vertebral arches, and costal processes of the embryonic vertebrae. The bodies are represented in yellow, the vertebral arches in red, and the costal processes in blue.

The Sternum.—The ventral ends of the ribs become united to one another by a longitudinal bar termed the **sternal plate**, and opposite the first seven pairs of ribs these sternal plates fuse in the middle line to form the manubrium and body of the sternum. The xiphoid process is formed by a backward extension of the sternal plates.

The Skull.—Up to a certain stage the development of the skull corresponds with that of the vertebral column; but it is modified later in association with the expansion of the brain-vesicles, the formation of the organs of smell, sight, and hearing, and the development of the mouth and pharynx.

The notochord extends as far forward as the anterior end of the mid-brain, and becomes partly surrounded by mesoderm (Fig. 98). The posterior part of this mesodermal investment corresponds with the basilar part of the occipital bone, and shows a subdivision into four segments, which are separated by the roots of the hypoglossal nerve. The mesoderm then extends over the brain-vesicles, and thus the

entire brain is enclosed by a mesodermal investment, which is termed the **membranous cranium**. From the inner layer of this the bones of the skull and the membranes of the brain are developed; from the outer layer the muscles, bloodvessels, true skin, and subcutaneous tissues of the scalp. In the shark and dog-fish this membranous cranium undergoes complete chondrification, and forms the cartilaginous skull or **chondrocranium** of these animals. In mammals, on the other hand, the process of chondrification is limited to the base of the skull—the roof and sides being covered in by membrane. Thus the bones of the base of the skull are preceded by cartilage, those of the roof and sides by membrane. The posterior part of the base of the skull is developed around the notochord, and exhibits a segmented

FIG. 98.—Sagittal section of cephalic end of notochord. (Keibel.)

condition analogous to that of the vertebral column, while the anterior part arises in front of the notochord and shows no regular segmentation. The base of the skull may therefore be divided into (a) a **chordal** or **vertebral**, and (b) a **prechordal** or **prevertebral** portion.

FIG. 99.—Diagrams of the cartilaginous cranium. (Wiedersheim.)

In the lower vertebrates two pairs of cartilages are developed, viz., a pair of **parachordal** cartilages, one on either side of the notochord; and a pair of **prechordal** cartilages, the **trabeculae cranii**, in front of the notochord (Fig. 99). The **parachordal cartilages** (Fig. 99) unite to form a **basilar plate**, from which the cartilaginous part of the occipital bone and the basi-sphenoid are developed. On the lateral aspects of the parachordal cartilages the auditory vesicles are situated,

and the mesoderm enclosing them is soon converted into cartilage, forming the **cartilaginous ear-capsules**. These cartilaginous ear-capsules, which are of an oval shape, fuse with the sides of the basilar plate, and from them arise the petrous and mastoid portions of the temporal bones. The **trabeculae cranii** (Fig. 99) are two curved bars of cartilage which embrace the hypophysis cerebri; their posterior ends soon unite with the basilar plate, while their anterior ends join to form the **ethmoidal plate**, which extends forward between the fore-brain and the olfactory pits. Later the trabeculae meet and fuse below the hypophysis, forming the floor

of the fossa hypophyseos and so cutting off the anterior lobe of the hypophysis from the stomodeum. The median part of the ethmoidal plate forms the bony and cartilaginous parts of the nasal septum. From the lateral margins of the trabeculae cranii three processes grow out on either side. The anterior forms the ethmoidal labyrinth and the lateral and alar cartilages of the nose; the middle gives rise to the small wing of the sphenoid, while from the posterior the great wing and lateral pterygoid plate of the sphenoid are developed (Figs. 100, 101). The bones of the vault are of membranous formation, and are termed **dermal** or **covering bones**. They are partly developed from the mesoderm of the membranous

eranium, and partly from that which lies outside the entoderm of the fore-gut. They comprise the upper part of the occipital squama (interparietal), the squamæ and tympanic parts of the temporals, the parietals, the frontal, the vomer, the medial pterygoid plates, and the bones of the face. Some of them remain distinct throughout life, *e. g.*, parietal and frontal, while others join with the bones of the chondrocranium, *e. g.*, interparietal, squamæ of temporals, and medial pterygoid plates.

Recent observations have shown that, in mammals, the basi-cranial cartilage, both in the chordal and prechordal regions of the base of the skull, is developed as a single plate which extends from behind forward. In man, however, its posterior part shows an indication of being developed from two chondrifying centres which fuse rapidly in front and below. The anterior and posterior thirds of the cartilage surround the notochord, but its middle third lies on the dorsal aspect of the notochord, which in this region is placed between the cartilage and the wall of the pharynx.

The Branchial or Visceral Arches and Pharyngeal Pouches.—In the lateral walls of the anterior part of the fore-gut five *pharyngeal pouches* appear (Fig. 104); each of the upper four pouches is prolonged into a dorsal and a ventral diverticulum. Over these pouches corresponding indentations of the ectoderm occur, forming what are known as the **branchial or outer pharyngeal grooves**. The intervening mesoderm is pressed aside and the ectoderm comes for a time into contact with the entodermal lining of the fore-gut, and the two layers unite along the floors of the grooves to form thin **closing membranes** between the fore-gut and the exterior. Later the mesoderm again penetrates between the entoderm and the ectoderm. In gill-bearing animals the closing membranes disappear, and the grooves become complete clefts, the **gill-clefts**, opening from the pharynx on to the exterior; perforation, however, does not occur in birds or mammals. The grooves separate a series of rounded bars or arches, the **branchial or visceral arches**, in which thickening of the mesoderm takes place (Figs. 102 and 103). The dorsal ends of these arches are attached to the sides of the head, while the ventral extremities ultimately meet in the middle line of the neck. In all, six arches make their appearance,

but of these only the first four are visible externally. The first arch is named the mandibular, and the second the hyoid; the others have no distinctive names. In each arch a cartilaginous bar, consisting of right and left halves, is developed, and with each of these there is one of the primitive aortic arches.

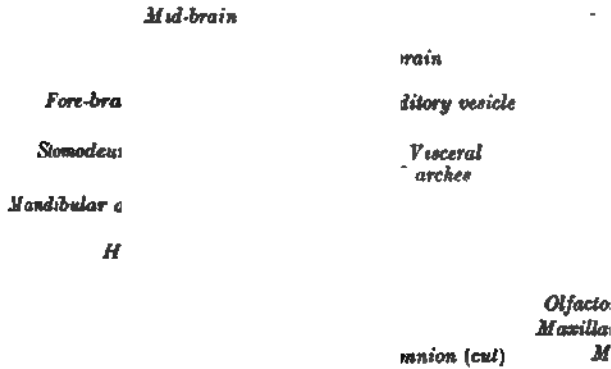

FIG. 102.—Embryo between eighteen and twenty-one days. (His.)

FIG. 103.—Head end of human embryo, about the end of the fourth week. (From model by Peter.)

The **mandibular arch** lies between the first branchial groove and the stomodeum; from it are developed the lower lip, the mandible, the muscles of mastication, and the anterior part of the tongue. Its cartilaginous bar is formed by what are known as **Meckel's cartilages** (right and left) (Fig. 105). The dorsal ends of these cartilages are connected with the ear-capsules and are ossified to form two of the bones of the middle ear, the malleus and incus; the ventral ends meet each other in the region of the symphysis menti, and are usually regarded as undergoing ossification to form that portion of the mandible which contains the incisor teeth. The intervening part of the cartilage disappears; the portion immediately adjacent to the malleus and incus is replaced by fibrous membrane, which constitutes the spheno-mandibular ligament, while from the connective tissue covering the remainder of the cartilage the greater part of the mandible is ossified. From the dorsal ends of the mandibular arch a triangular process, the **maxillary process**, grows forward on either side and forms the cheek and lateral part of the upper lip. The **second** or **hyoid arch** assists in forming the side and front of the neck. From its cartilage are developed the styloid process, stylohyoid ligament, and lesser cornu of the hyoid bone. The cartilage of the **third arch** gives origin to the greater cornu of the hyoid bone. The ventral ends of the second and third arches unite with those of the opposite side, and form a transverse band, from which the body of

the hyoid bone and the posterior part of the tongue are developed. The ventral portions of the cartilages of the fourth and fifth arches unite to form the thyroid cartilage; from the cartilages of the sixth arch the cricoid and arytenoid cartilages and the cartilages of the trachea are developed. The mandibular and hyoid arches grow more rapidly than those behind them, with the result that the latter

become, to a certain extent, telescoped within the former, and a deep depression, the *sinus cervicalls*, is formed on either side of the neck. This sinus is bounded in front by the hyoid arch, and behind by the thoracic wall; it is ultimately obliterated by the fusion of its walls.

From the first branchial groove the concha auriculæ and external acoustic meatus are developed, while around the groove there appear, on the mandibular and hyoid arches, a number of swellings from which the auricula or pinna is formed. The first pharyngeal pouch is prolonged dorsally to form the auditory tube and the tympanic cavity; the closing membrane between the mandibular and hyoid arches

is invaded by mesoderm, and forms the tympanic membrane. No traces of the second, third, and fourth branchial grooves persist. The inner part of the second pharyngeal pouch is named the *sinus tonsillaris*; in it the tonsil is developed, above which a trace of the sinus persists as the supratonsillar fossa. The fossa of Rosenmüller or lateral recess of the pharynx is by some regarded as a persistent part of the second pharyngeal pouch, but it is probably developed as a secondary formation. From the third pharyngeal pouch the thymus arises as an entodermal diverticulum on either side, and from the fourth pouches small diverticula project and become incorporated with the thymus, but in man these diverticula probably never form true thymus tissue. The parathyroids also arise as diverticula from the third and fourth pouches. From the fifth pouches the ultimobranchial bodies originate and are enveloped by the lateral prolongations of the median thyroid rudiment; they do not, however, form true thyroid tissue, nor are any traces of them found in the human adult.

FIG. 108.—Same embryo as shown in Fig. 107, with front wall of pharynx removed.

The Nose and Face.—During the third week two areas of thickened ectoderm, the **olfactory areas**, appear immediately under the fore-brain in the anterior wall of the stomodeum, one on either side of a region termed the **fronto-nasal process** (Fig. 106). By the upgrowth of the surrounding parts these areas are converted into pits, the **olfactory pits**, which indent the fronto-nasal process and divide it into a **medial** and two **lateral nasal processes** (Fig. 107). The rounded lateral angles of the medial process constitute the **globular processes** of His. The olfactory pits form the rudiments of the nasal cavities, and from their ectodermal lining the epithelium of the nasal cavities, with the exception of that of the inferior meatuses, is derived. The globular processes are prolonged backward as plates, termed the **nasal laminae**; these laminae are at first some distance apart, but, gradually approaching, they ultimately fuse and form the nasal septum; the processes themselves meet in the middle line, and form the premaxillae and the philtrum or central part of the upper lip (Fig. 110). The depressed part of the medial nasal process between the globular processes forms the lower part of the nasal septum or **columella**; while above this is seen a prominent angle, which becomes the future

apex (Figs. 107, 108), and still higher a flat area, the future bridge, of the nose. The lateral nasal processes form the alæ of the nose.

Continuous with the dorsal end of the mandibular arch, and growing forward from its cephalic border, is a triangular process, the **maxillary process**, the ventral extremity of which is separated from the mandibular arch by a > shaped notch (Fig. 106). The maxillary process forms the lateral wall and floor of the orbit, and in it are ossified the zygomatic bone and the greater part of the maxilla; it meets with the lateral nasal process, from which, however, it is separated for a time by a groove, the **naso-optic furrow**, that extend from the furrow encircling the eyeball to the olfactory pit. The maxillary processes ultimately fuse with the lateral nasal and globular processes, and form the lateral parts of the upper lip and the posterior boundaries of the nares (Figs. 109, 110). From the third to the fifth month the nares are filled by masses of epithelium, on the breaking down and disappearance of which the permanent openings are produced. The maxillary process also gives rise to the lower portion of the lateral wall of the nasal cavity.

FIG. 109. —Head of a human embryo of about eight weeks, in which the nose and mouth are formed. (His.)

FIG. 110. —Diagram showing the regions of the adult face and neck related to the fronto-nasal process and the branchial arches.

The roof of the nose and the remaining parts of the lateral wall, viz., the ethmoidal labyrinth, the inferior nasal concha, the lateral cartilage, and the lateral crus of the alar cartilage, are developed in the lateral nasal process. By the fusion of the maxillary and nasal processes in the roof of the stomodeum the **primitive palate** (Fig. 111) is formed, and the olfactory pits extend backward above it. The posterior end of each pit is closed by an epithelial membrane, the **bucconasal membrane**, formed by the apposition of the nasal and stomodeal epithelium. By the rupture of these membranes the **primitive choanae** or openings between the olfactory pits and the stomodeum are established. The floor of the nasal cavity is completed by the development of a pair of shelf-like **palatine processes** which extend medialward from the maxillary processes (Figs. 112 and 113); these coalesce with each other in the middle line, and constitute the entire palate, except a small part in front which is formed by the premaxillary bones. Two apertures persist for a time between the palatine processes and the premaxillæ and represent the permanent channels which in the lower animals connect the nose and mouth. The union of the parts which form the palate commences in front, the premaxillary and palatine processes joining in the eighth week, while the region of the future hard palate is completed by the ninth, and that of the soft palate by the eleventh week. By

the completion of the palate the permanent choanæ are formed and are situated a considerable distance behind the primitive choanæ. The deformity known as cleft palate results from a non-union of the palatine processes, and that of hare-lip through a non-union of the maxillary and globular processes (see page 299). The nasal cavity becomes divided by a vertical septum, which extends downward and backward from the medial nasal process and nasal laminae, and unites below with the palatine processes. Into this septum a plate of cartilage extends from

*Nasal
cavity*

FIG. 111.—Primitive palate of a human embryo of thirty-seven to thirty-eight days. (From model by Peter)
On the left side the lateral wall of the nasal cavity has been removed.

the under aspect of the ethmoid plate of the chondrocranium. The anterior part of this cartilaginous plate persists as the septal cartilage of the nose and the medial crus of the alar cartilage, but the posterior and upper parts are replaced by the vomer and perpendicular plate of the ethmoid. On either side of the nasal septum, at its lower and anterior part, the ectoderm is invaginated to form a blind pouch or diverticulum, which extends backward and upward into the nasal septum and

FIG. 112.—The roof of the mouth of a human embryo, aged about two and a half months, showing the mode of formation of the palate. (Hae.)

is supported by a curved plate of cartilage. These pouches form the rudiments of the vomero-nasal organs of Jacobson, which open below, close to the junction of the premaxillary and maxillary bones.

The Limbs.—The limbs begin to make their appearance in the third week as small elevations or buds at the side of the trunk (Fig. 114). Prolongations from the muscle- and cutis-plates of several primitive segments extend into each bud, and carry with them the anterior divisions of the corresponding spinal nerves.

The nerves supplying the limbs indicate the number of primitive segments which contribute to their formation—the upper limb being derived from seven, viz., fourth cervical to second thoracic inclusive, and the lower limb from ten, viz., twelfth thoracic to fourth sacral inclusive. The axial part of the mesoderm of the limb-bud becomes condensed and converted into its cartilaginous skeleton, and by the ossification of this the bones of the limbs are formed. By the sixth week the three chief divisions of the limbs are marked off by furrows—the upper into arm, forearm, and hand; the lower into thigh, leg, and foot (Fig. 115). The limbs are at first directed backward nearly parallel to the long axis of the trunk, and each presents two surfaces and two borders. Of the surfaces, one—the future *flexor* surface of the limb—is directed ventrally; the other, the *extensor* surface, dorsally; one border, the *preaxial*, looks forward toward the cephalic end of the embryo, and the other, the *postaxial*, backward toward the caudal end. The lateral epicondyle of the humerus, the radius, and the thumb lie along the preaxial border

FIG. 113.—Frontal section of nasal cavities of a human embryo 28 mm. long. (Kollmann.)

of the upper limb; and the medial epicondyle of the femur, the tibia, and the great toe along the corresponding border of the lower limb. The preaxial part is derived from the anterior segments, the postaxial from the posterior segments of the limb-bud; and this explains, to a large extent, the innervation of the adult limb, the nerves of the more anterior segments being distributed along the preaxial (radial or tibial), and those of the more posterior along the postaxial (ulnar or fibular) border of the limb. The limbs next undergo a rotation or torsion through an angle of 90° around their long axes the rotation being effected almost entirely at the limb girdles. In the upper limb the rotation is outward and forward; in the lower limb, inward and backward. As a consequence of this rotation the preaxial (radial) border of the fore-limb is directed lateralward, and the preaxial (tibial) border of the hind-limb is directed medialward; thus the flexor surface of the fore-limb is turned forward, and that of the hind-limb backward.

DEVELOPMENT OF THE JOINTS.

The mesoderm from which the different parts of the skeleton are formed at first shows no differentiation into masses corresponding with the individual bones. Thus continuous cores of mesoderm form the axes of the limb-buds and a continuous column of mesoderm the future vertebral column. The first indications of the bones and joints are circumscribed condensations of the mesoderm; these condensed parts become chondrified and finally ossified to form the bones of the skeleton. The intervening non-condensed portions consist at first of undifferentiated mesoderm, which may develop in one of three directions. It may be converted into fibrous tissue as in the case of the skull bones, a synarthrodial joint being the result, or it may become partly cartilaginous, in which case an amphiarthrodial joint is formed. Again, it may become looser in texture and a cavity ultimately appear in its midst; the cells lining the sides of this cavity form a synovial membrane and thus a diarthrodial joint is developed.

FIG. 114.—Human embryo from thirty-one to thirty-four days. (His.)

FIG. 115.—Embryo of about six weeks. (His.)

The tissue surrounding the original mesodermal core forms fibrous sheaths for the developing bones, *i. e.*, periosteum and perichondrium, which are continued between the ends of the bones over the synovial membrane as the capsules of the joints. These capsules are not of uniform thickness, so that in them may be recognized especially strengthened band which are described as ligaments. This, however, is not the only method of formation of ligaments. In some cases by modification of, or derivations from, the tendons surrounding the joint, additional ligamentous bands are provided to further strengthen the articulations.

In several of the movable joints the mesoderm which originally existed between the ends of the bones does not become completely absorbed—a portion of it persists and forms an articular disk. These disks may be intimately associated in their development with the muscles surrounding the joint, *e. g.*, the menisci of the knee-joint, or with cartilaginous elements, representatives of skeletal structures, which are vestigial in human anatomy, *e. g.*, the articular disk of the sterno-clavicular joint.

DEVELOPMENT OF THE MUSCLES.

The voluntary muscles are developed from the myotomes of the primitive segments. Portions of the myotomes retain their position on the sides of the neural tube, where they may remain distinct from each other and form the short muscles of the vertebral column, or fuse with corresponding portions of neighboring myotomes to form the Sacrospinales and their continuations. Other portions of the myotomes extend into the trunk wall, where again they may retain their segmental condition, as in the Intercostales, or may fuse with adjacent segments to form the flat muscles of the abdominal wall. Finally, portions of the myotomes wander into the limb-buds and there undergo fusions and alterations in form to produce the limb muscles. The original segmental character of the limb muscles is therefore lost, but their segmental nerve supplies are retained. Some of the limb muscles expand and migrate secondarily toward the mid-dorsal line, *e. g.*, Trapezius and Latissimus dorsi, or toward the mid-ventral line, *e. g.*, Pectoralis major. Again, muscles may migrate in a cephalic direction, *e. g.*, the facial muscles which are derived from the hyoid arch, or in a caudal direction, *e. g.*, the Serratus anterior. In all cases the muscles carry with them the segmental nerves of the myotomes from which they were originally derived; two examples of this will suffice, viz., the Diaphragma, which is derived from the third and fourth and the Serratus anterior, from the fifth, sixth, and seventh cervical segments as is indicated by their nerves of supply. In man and the higher vertebrates many of the derivatives of the myotomes degenerate and are converted into aponeuroses, *e. g.*, galea aponeurotica, and the aponeuroses of the abdominal muscles, or ligaments, *e. g.*, sacrotuberous ligament and fibular collateral ligament of the knee.

The involuntary muscles are derived from the splanchnopleure mesoderm.

DEVELOPMENT OF THE SKIN, GLANDS, AND SOFT PARTS.

The epidermis and its appendages, consisting of the hairs, nails, sebaceous and sweat glands, are developed from the ectoderm, while the corium or true skin is of mesodermal origin, being derived from the cutis-plates of the primitive segments. About the fifth week the epidermis consists of two layers of cells, the deeper one corresponding to the rete mucosum. The subcutaneous fat appears about the fourth month, and the papillæ of the true skin about the sixth. A considerable desquamation of epidermis takes place during fetal life, and this desquamated epidermis, mixed with sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of fetal life. The nails are formed at the third month, and begin to project from the epidermis about the sixth. The hairs appear between the third and fourth months in the form of solid downgrowths of the deeper layer of the epidermis, the growing extremities of which become inverted by papillary projections from the corium. The central cells of the solid downgrowths undergo alteration to form the hair, while the peripheral cells are retained to form the lining cells of the hair-follicle. About the fifth month the fetal hairs (*lanugo*) appear, first on the head and then on the other parts; they drop off after birth, and give place to the permanent hairs. The cellular structures of the sudoriferous and sebaceous glands are formed from the ectoderm, while the connective tissue and bloodvessels are derived from the mesoderm.

The *mamma* is also formed partly from mesoderm and partly from ectoderm—its bloodvessels and connective tissue being derived from the former, its cellular elements from the latter. Its first rudiment is seen about the third month, in the

form of a number of small inward projections of the ectoderm, which invade the mesoderm; from these, secondary tracts of cellular elements radiate and subsequently give rise to the epithelium of the glandular follicles and ducts. The development of the follicles, however, remains imperfect, except in the parous female.

DEVELOPMENT OF THE NERVOUS SYSTEM AND SENSE ORGANS.

The entire nervous system is of ectodermal origin, and its first rudiment is seen in the neural groove which extends along the dorsal aspect of the embryo (Fig. 75). By the elevation and ultimate fusion of the neural folds, the groove is converted into the neural tube (Fig. 77). The anterior end of the neural tube becomes expanded to form the three primary brain-vesicles; the cavity of the tube is subsequently modified to form the ventricular cavities of the brain, and the central canal of the medulla spinalis; from the wall the nervous elements and the neuroglia of the brain and medulla spinalis are developed.

neural root

al

layer

r

neural roots

ger

FIG. 116.—Section of medulla spinalis of a four weeks' embryo. (Hls.)

The Medulla Spinalis.—At first the wall of the neural tube is composed of a single layer of columnar ectodermal cells. Soon the side-walls become thickened, while the dorsal and ventral parts remain thin, and are named the **roof-** and **floor-plates** (Figs. 116, 118). A transverse section of the tube at this stage presents an oval outline, while its lumen has the appearance of a slit. The cells which constitute the wall of the tube proliferate rapidly, lose their cell-boundaries and form a syncytium. This syncytium consists at first of dense protoplasm with closely packed nuclei, but later it opens out and forms a looser meshwork with the cellular strands arranged in a radiating manner from the central canal. Three layers may now be defined—an internal or **ependymal**, an intermediate or **mantle**, and an external or **marginal**. The **ependymal layer** is ultimately converted into the **ependyma** of the central canal; the processes of its cells pass outward toward the periphery of the medulla spinalis. The **marginal layer** is devoid of nuclei, and later forms the supporting framework for the white funiculi of the medulla spinalis. The **mantle layer** represents the whole of the future gray columns of the medulla

spinalis; in it the cells are differentiated into two sets, viz., (a) **spongioblasts** or **young neuroglia cells**, and (b) **germinal cells**, which are the parents of the **neuroblasts** or **young nerve cells** (Fig. 117). The spongioblasts are at first connected to one another by filaments of the syncytium; in these, fibrils are developed, so that as the

Germinal cell
.. ..

FIG. 117.—Transverse section of the medulla spinalis of a human embryo at the beginning of the fourth week. (After His.) The left edge of the figure corresponds to the lining of the central canal.

neuroglial cells become defined they exhibit their characteristic mature appearance with multiple processes proceeding from each cell. The germinal cells are large, round or oval, and first make their appearance between the ependymal cells on the sides of the central canal. They increase rapidly in number, so that by the

FIG. 118.—Transverse sections through the medullas spinales of human embryos. A. Aged about four and a half weeks. B. Aged about three months. (His.)

fourth week they form an almost continuous layer on each side of the tube. No germinal cells are found in the roof- or floor-plates; the roof-plate retains, in certain regions of the brain, its epithelial character; elsewhere, its cells become spongioblasts. By subdivision the germinal cells give rise to the neuroblasts or young

nerve cells, which migrate outward from the sides of the central canal into the mantle layer and neural crest, and at the same time become pear-shaped; the tapering part of the cell undergoes still further elongation, and forms the axis-cylinder of the cell.

The lateral walls of the medulla spinalis continue to increase in thickness, and the canal widens out near its dorsal extremity, and assumes a somewhat lozenge-shaped appearance. The widest part of the canal serves to subdivide the lateral wall of the neural tube into a **dorsal** or **alar**, and a **ventral** or **basal lamina** (Fig. 118), a subdivision which extends forward into the brain. At a later stage the ventral part of the canal widens out, while the dorsal part is first reduced to a mere slit and then becomes obliterated by the approximation and fusion of its walls; the ventral part of the canal persists and forms the central canal of the adult medulla spinalis. The caudal end of the canal exhibits a conical expansion which is known as the **terminal ventricle**.

The ventral part of the mantle layer becomes thickened, and on cross-section appears as a triangular patch between the marginal and ependymal layers. This thickening is the rudiment of the anterior column of gray substance, and contains many neuroblasts, the axis-cylinders of which pass out through the marginal layer and form the anterior roots of the spinal nerves (Figs. 116, 118). The thickening of the mantle layer gradually extends in a dorsal direction, and forms the posterior column of gray substance. The axons of many of the neuroblasts in the alar lamina run forward, and cross in the floor-plate to the opposite side of the medulla spinalis; these form the rudiment of the anterior white commissure.

About the end of the fourth week nerve fibres begin to appear in the marginal layer. The first to develop are the short intersegmental fibres from the neuroblasts in the mantle zone, and the fibres of the dorsal nerve roots which grow into the medulla spinalis from the cells of the spinal ganglia. By the sixth week these dorsal root fibres form a well-defined **oval bundle** in the peripheral part of the alar lamina; this bundle gradually increases in size, and spreading toward the middle line forms the rudiment of the posterior funiculus. The long intersegmental fibres begin to appear about the third month and the cerebrospinal fibres about the fifth month. All nerve fibres are at first destitute of medullary sheaths. Different groups of fibres receive their sheaths at different times—the dorsal and ventral nerve roots about the fifth month, the cerebrospinal fibres after the ninth month.

By the growth of the anterior columns of gray substance, and by the increase in size of the anterior funiculi, a furrow is formed between the lateral halves of the cord anteriorly; this gradually deepens to form the anterior median fissure. The mode of formation of the posterior septum is somewhat uncertain. Many believe that it is produced by the growing together of the walls of the posterior part of the central canal and by the development from its ependymal cells of a septum of fibrillated tissue which separates the future funiculi graciles.

Up to the third month of fetal life the medulla spinalis occupies the entire length of the vertebral canal, and the spinal nerves pass outward at right angles to the medulla spinalis. From this time onward, the vertebral column grows more rapidly than the medulla spinalis, and the latter, being fixed above through its continuity with the brain, gradually assumes a higher position within the canal. By the sixth month its lower end reaches only as far as the upper end of the sacrum; at birth it is on a level with the third lumbar vertebra, and in the adult with the lower border of the first or upper border of the second lumbar vertebra. A delicate filament, the **filum terminale**, extends from its lower end as far as the coccyx.

The Spinal Nerves.—Each spinal nerve is attached to the medulla spinalis by an anterior or ventral and a posterior or dorsal root.

The fibres of the anterior roots are formed by the axons of the neuroblasts which lie in the ventral part of the mantle layer; these axons grow out through the

overlying marginal layer and become grouped to form the anterior nerve root (Fig. 117).

The fibres of the posterior roots are developed from the cells of the spinal ganglia. Before the neural groove is closed to form the neural tube a ridge of ectodermal cells, the **ganglion ridge** or **neural crest** (Fig. 119), appears along the prominent margin of each neural fold. When the folds meet in the middle line the two ganglion ridges fuse and form a wedge-shaped area along the line of closure of the tube. The cells of this area proliferate rapidly opposite the primitive segments and then migrate in a lateral and ventral direction to the sides of the neural tube, where they ultimately form a series of oval-shaped masses, the future spinal ganglia. These ganglia are arranged symmetrically on the two sides of the neural tube and, except in the region of the tail, are equal in number to the primitive segments. The cells of the ganglia, like the cells of the mantle layer, are of two kinds, viz., **spongioblasts** and **neuroblasts**. The spongioblasts develop into the neuroglial cells of the ganglia. The neuroblasts are at first round or oval in shape, but soon assume the form of spindles the extremities of which gradually elongate into central and

peripheral processes. The central processes grow medialward and, becoming connected with the neural tube, constitute the fibres of the posterior nerve roots, while the peripheral processes grow lateralward to mingle with the fibres of the anterior root in the spinal nerve. As development proceeds the original bipolar form of the cells changes; the two processes become approximated until they ultimately arise from a single stem in a T-shaped manner. Only in the ganglia of the acoustic nerve is the bipolar form retained. More recent observers hold, however, that the T-form is derived from the branching of a single process which grows out from the cell.

The anterior or ventral and the posterior or dorsal nerve roots join immediately beyond the spinal ganglion to form the **spinal nerve**, which then divides into anterior, posterior, and visceral divisions. The anterior and posterior divisions proceed directly to their areas of distribution without further association with ganglion cells (Fig. 120). The visceral divisions are distributed to the thoracic, abdominal, and pelvic viscera, to reach which they pass through the sympathetic trunk, and many of the fibres form arborizations around the ganglion cells of this trunk. Visceral branches are not given off from all the spinal nerves; they form two groups, viz., (a) **thoracico-lumbar**, from the first or second thoracic, to the second or third lumbar nerves; and (b) **pelvic**, from the second and third, or third and fourth sacral nerves.

FIG. 119.—Two stages in the development of the neural crest in the human embryo. (Lenhossek.)

The Brain.—The brain is developed from the anterior end of the neural tube, which at an early period becomes expanded into three vesicles, the primary cerebral vesicles (Fig. 76). These are marked off from each other by intervening constrictions, and are named the **prosencephalon** or **fore-brain**, the **mesencephalon** or **mid-brain**, and the **rhombencephalon** or **hind-brain**—the last being continuous with the medulla spinalis. As the result of unequal growth of these different parts three flexures are formed and the embryonic brain becomes bent on itself

in a somewhat zigzag fashion; the two earliest flexures are concave ventrally and are associated with corresponding flexures of the whole head. The first flexure appears in the region of the mid-brain, and is named the **ventral cephalic flexure** (Fig. 125). By means of it the fore-brain is bent in a ventral direction around the anterior end of the notochord and fore-gut, with the result that the floor of the fore-brain comes to lie almost parallel with that of the hind-brain. This flexure causes the mid-brain to become, for a time, the most prominent part of

the brain, since its dorsal surface corresponds with the convexity of the curve. The second bend appears at the junction of the hind-brain and medulla spinalis. This is termed the **cervical flexure** (Fig. 127), and increases from the third to the end of the fifth week, when the hind-brain forms nearly a right angle with the medulla spinalis; after the fifth week erection of the head takes place and the cervical flexure diminishes and disappears. The third bend is named the **pontine flexure** (Fig. 127), because it is found in the region of the future pons Varoli. It differs

from the other two in that (a) its convexity is forward, and (b) it does not affect the head. The lateral walls of the brain-tube, like those of the medulla spinalis, are divided by internal furrows into alar or dorsal and basal or ventral laminae (Fig. 121).

FIG. 121.—Diagram to illustrate the alar and basal laminae of brain vesicles. (His.)

FIG. 122.—Transverse section of medulla oblongata of human embryo. $\times 32$. (Kollmann.)

The Rhombencephalon or Hind-brain.—The cavity of the hind-brain becomes the fourth ventricle. At the time when the ventral cephalic flexure makes its appearance, the length of the hind-brain exceeds the combined lengths of the other two vesicles. Immediately behind the mid-brain it exhibits a marked constriction, the *isthmus rhombencephali* (Fig. 125, *Isthmus*), which is best seen when the brain is viewed from the dorsal aspect. From the isthmus the anterior medullary velum

and the brachia conjunctiva of the cerebellum are formed. It is customary to divide the rest of the hind-brain into two parts, viz., an upper, called the *metencephalon*, and a lower, the *myelencephalon*. The cerebellum is developed by a thickening of the roof, and the pons by a thickening in the floor and lateral walls of the metencephalon. The floor and lateral walls of the myelencephalon are

thickened to form the medulla oblongata; its roof remains thin, and, retaining to a great extent its epithelial nature, is expanded in a lateral direction. Later, by the growth and backward extension of the cerebellum, the roof is folded inward toward the cavity of the fourth ventricle; it assists in completing the dorsal wall of this cavity, and is also invaginated to form the ependymal covering of its choroid plexuses. Above it is continuous with the posterior medullary velum; below, with the obex and ligulae.

FIG. 124.—Hind-brain of a human embryo of three months—viewed from behind and partly from left side. (From model by His.)

FIG. 125.—Exterior of brain of human embryo of four and a half weeks. (From model by His.)

The development of the **medulla oblongata** resembles that of the medulla spinalis, but at the same time exhibits one or two interesting modifications. On transverse section the myelencephalon at an early stage is seen to consist of two lateral walls, connected across the middle line by floor- and roof-plates (Figs. 122 and 123). Each lateral wall consists of an alar and a basal lamina, separated by an internal furrow, the remains of which are represented in the adult brain by the sulcus limitans on the rhomboid fossa. The contained cavity is more or less triangular in outline, the base being formed by the roof-plate, which is thin and greatly expanded transversely. Pear-shaped neuroblasts are developed in the alar and basal laminae, and their narrow stalks are elongated to form the axis-cylinders of the nerve fibres. Opposite the furrow or boundary between the alar and basal laminae a bundle of nerve fibres attaches itself to the outer surface of the alar lamina. This is named the **tractus solitarius** (Fig. 123), and is formed by the sensory fibres of the glossopharyngeal and vagus nerves. It is the homologue of the **oval bundle** seen in the medulla spinalis, and, like it, is developed by an ingrowth of fibres from the ganglia of the neural crest. At first it is applied to the outer surface of the alar lamina, but it soon becomes buried, owing to the growth over it of the neighboring parts. By the fifth week the dorsal part of the alar lamina bends in a lateral direction along its entire length, to form what is termed the **rhombic lip** (Figs. 123, 124). Within a few days this lip becomes applied to, and unites

with, the outer surface of the main part of the alar lamina, and so covers in the tractus solitarius and also the spinal root of the trigeminal nerve; the nodulus and flocculus of the cerebellum are developed from the rhombic lip.

Neuroblasts accumulate in the mantle layer; those in the basal lamina correspond with the cells in the anterior gray column of the medulla spinalis, and, like them, give origin to motor nerve fibres; in the medulla oblongata they are, however, arranged in groups or nuclei, instead of forming a continuous column. From the alar lamina and its rhombic lip, neuroblasts migrate into the basal lamina, and become aggregated to form the olivary nuclei, while many send their axis-cylinders through the floor-plate to the opposite side, and thus constitute the rudiment of the raphé of the medulla oblongata. By means of this thickening of the ventral portion, the motor nuclei are buried deeply in the interior, and, in the adult, are found close to the rhomboid fossa. This is still further accentuated: (a) by the

development of the pyramids, which are formed about the fourth month by the downward growth of the motor fibres from the cerebral cortex; and (b) by the fibres which pass to and from the cerebellum. On the rhomboid fossa a series of six temporary furrows appears; these are termed the **rhombic grooves**. They bear a definite relationship to certain of the cerebral nerves; thus, from before backward the first and second grooves overlie the nucleus of the trigeminal; the third, the nucleus of the facial; the fourth, that of the abducent; the fifth, that of the glossopharyngeal; and the sixth, that of the vagus.

The **pons** is developed from the ventro-lateral wall of the metencephalon by a process similar to that which has been described for the medulla oblongata.

The **cerebellum** is developed in the roof of the anterior part of the hind-brain (Figs. 124 to 129).

The alar laminae of this region become thickened to form two

lateral plates which soon fuse in the middle line and produce a thick lamina which roofs in the upper part of the cavity of the hind-brain vesicle; this constitutes the rudiment of the cerebellum, the outer surface of which is originally smooth and convex. The fissures of the cerebellum appear first in the vermis and floccular region, and traces of them are found during the third month; the fissures on the cerebellar hemispheres do not appear until the fifth month. The primitive fissures are not developed in the order of their relative size in the adult—thus the horizontal sulcus in the fifth month is merely a shallow groove. The best marked of the early fissures are: (a) the **fissura prima** between the developing culmen and declive, and (b) the **fissura secunda** between the future pyramid and uvula. The flocculus and nodule are developed from the rhombic lip, and are therefore recognizable as separate portions before any of the other cerebellar lobules. The groove produced by the bending over of the rhombic lip is here known as the

FIG. 126.—Brain of human embryo of four and a half weeks, showing interior of fore-brain. (From model by His.)

floccular fissure; when the two lateral walls fuse, the right and left floccular fissures join in the middle line and their central part becomes the **post-nodular fissure**.

On the ventricular surface of the cerebellar lamina a transverse furrow, the **incisura fastigii**, appears, and deepens to form the tent-like recess of the roof of the fourth ventricle. The rudiment of the cerebellum at first projects in a dorsal direction; but, by the backward growth of the cerebrum, it is folded downward and somewhat flattened, and the thin roof-plate of the fourth ventricle, originally continuous with the posterior border of the cerebellum, is projected inward toward the cavity of the ventricle.

The Mesencephalon or Mid-brain.—The mid-brain (Figs. 125 to 129) exists for a time as a thin-walled cavity of some size, and is separated from the isthmus rhomencephali behind, and from the fore-brain in front, by slight constrictions. Its cavity becomes relatively reduced in diameter, and forms the cerebral aqueduct of the adult brain. Its basal laminae increase in thickness to form the cerebral peduncles, which are at first of small size, but rapidly enlarge after the fourth month.

Ganglion habenulae

4

FIG. 127.—Exterior of brain of human embryo of five weeks. (From model by His.)

The neuroblasts of these laminae are grouped in relation to the sides and floor of the cerebral aqueduct, and constitute the nuclei of the oculomotor and trochlear nerves, and of the mesencephalic root of the trigeminal nerve. By a similar thickening process its alar laminae are developed into the quadrigeminal lamina. The dorsal part of the wall for a time undergoes expansion, and presents an internal median furrow and a corresponding external ridge; these, however, disappear, and the latter is replaced by a groove. Subsequently two oblique furrows extend medialward and backward, and the thickened lamina is thus subdivided into the superior and inferior colliculi.

The Prosencephalon or Fore-brain.—A transverse section of the early fore-brain shows the same parts as are displayed in similar sections of the medulla spinalis and medulla oblongata, viz., a pair of thick lateral walls connected by thin floor- and roof-plates. Moreover, each lateral wall exhibits a division into a dorsal or alar and a ventral or basal lamina separated internally by a furrow termed the **sulcus**

of Monro. This sulcus ends anteriorly at the medial end of the optic stalk, and in the adult brain is retained as a slight groove extending backward from the interventricular foramen to the cerebral aqueduct.

At a very early period—in some animals before the closure of the cranial part of the neural tube—two lateral diverticula, the **optic vesicles**, appear, one on either side of the fore-brain; for a time they communicate with the cavity of the fore-brain by relatively wide openings. The peripheral parts of the vesicles expand, while the proximal parts are reduced to tubular stalks, the **optic stalks**. The optic vesicle gives rise to the retina and the epithelium on the back of the ciliary body and iris; the optic stalk is invaded by nerve fibres to form the optic nerve. The fore-brain then grows forward, and from the alar laminae of this front portion the cerebral hemispheres originate as diverticula which rapidly expand to form two large pouches, one on either side. The cavities of these diverticula are the rudiments of the lateral ventricles; they communicate with the median part of the fore-brain cavity by relatively wide openings, which ultimately form the interventricular

Recess

C

Cervical flexure

FIG. 123.—Interior of brain of human embryo of five weeks. (From model by His.)

foramen. The median portion of the wall of the fore-brain vesicle consists of a thin lamina, the **lamina terminalis** (Figs. 129, 132), which stretches from the interventricular foramen to the recess at the base of the optic stalk. The anterior part of the fore-brain, including the rudiments of the cerebral hemispheres, is named the **telencephalon**, and its posterior portion is termed the **diencephalon**; both of these contribute to the formation of the third ventricle.

The Diencephalon.—From the alar lamina of the diencephalon, the **thalamus**, **metathalamus**, and **epithalamus** are developed. The **thalamus** (Figs. 125 to 129) arises as a thickening which involves the anterior two-thirds of the alar lamina. The two thalami are visible, for a time, on the surface of the brain, but are subsequently hidden by the cerebral hemispheres which grow backward over them. The thalami extend medialward and gradually narrow the cavity between them into a slit-like aperture which forms the greater part of the third ventricle; their medial surfaces ultimately adhere, in part, to each other, and the **intermediate**

mass of the ventricle is developed across the area of contact. The *metathalamus* comprises the geniculate bodies which originate as slight outward bulgings of the alar lamina. In the adult the lateral geniculate body appears as an eminence on the lateral part of the posterior end of the thalamus, while the medial is situated on the lateral aspect of the mesencephalon. The *epithalamus* includes the pineal body, the posterior commissure, and the trigonum habenulae. The pineal body arises as an upward evagination of the roof-plate immediately in front of the mid-brain; this evagination becomes solid with the exception of its proximal part, which persists as the recessus pinealis. In lizards the pineal evagination is elongated into a stalk, and its peripheral extremity is expanded into a vesicle, in which a rudimentary lens and retina are formed; the stalk becomes solid and nerve fibres make their appearance in it, so that in these animals the pineal body forms a rudimentary eye. The posterior commissure is formed by the ingrowth of fibres into the depression behind and below the pineal evagination, and the trigonum habenulae is developed in front of the pineal recess.

Choroidal fissure

1

FIG. 129.—Median sagittal section of brain of human embryo of three months. (From model by His.)

From the basal laminae of the diencephalon the *pars mamillaria hypothalami* is developed; this comprises the corpora mamillaria and the posterior part of the tuber cinereum. The corpora mamillaria arise as a single thickening, which becomes divided into two by a median furrow during the third month.

The roof-plate of the diencephalon, in front of the pineal body, remains thin and epithelial in character, and is subsequently invaginated by the choroid plexuses of the third ventricle.

The Telencephalon.—This consists of a median portion and two lateral diverticula. The median portion forms the anterior part of the cavity of the third ventricle, and is closed below and in front by the lamina terminalis. The lateral diverticula consist of outward pouchings of the alar laminae; the cavities represent the lateral ventricles, and their walls become thickened to form the nervous

matter of the cerebral hemispheres. The roof-plate of the telencephalon remains thin, and is continuous in front with the lamina terminalis and behind with the roof-plate of the diencephalon. In the basal laminae and floor-plate the *pars optica hypothalami* is developed; this comprises the anterior part of the tuber cinereum, the infundibulum and posterior lobe of the hypophysis, and the optic chiasma. The anterior part of the tuber cinereum is derived from the posterior part of the floor of the telencephalon; the infundibulum and posterior lobe of the hypophysis arise as a downward diverticulum from the floor. The most dependent part of the diverticulum becomes solid and forms the posterior lobe of the hypophysis; the anterior lobe of the hypophysis is developed from a diverticulum of the ectodermal lining of the stomodeum (page 166). The optic chiasma is formed by the meeting and partial decussation of the optic nerves, which subsequently grow backward as the optic tracts and end in the diencephalon.

The cerebral hemispheres arise as diverticula of the alar laminae of the telencephalon (Figs. 125 to 129); they increase rapidly in size and ultimately overlap the structures developed from the mid- and hind-brains. This great expansion

of the hemispheres is a characteristic feature of the brains of mammals, and attains its maximum development in the brain of man. Elliott-Smith divides each cerebral hemisphere into three fundamental parts, viz., the *rhinencephalon*, the *corpus striatum*, and the *neopallium*.

The *rhinencephalon* (Fig. 130) represents the oldest part of the telencephalon, and forms almost the whole of the hemisphere in fishes, amphibians, and reptiles. In man it is feebly developed in comparison with the rest of the hemisphere, and comprises the following parts, viz., the olfactory lobe (con-

Fig. 130.—Inferior surface of brain of embryo at beginning of fourth month. (From Kollmann.)

sisting of the olfactory tract and bulb and the trigonum olfactorium), the anterior perforated substance, the septum pellucidum, the subcallosal, supracallosal, and dentate gyri, the fornix, the hippocampus, and the uncus. The rhinencephalon appears as a longitudinal elevation, with a corresponding internal furrow, on the under surface of the hemisphere close to the lamina terminalis; it is separated from the lateral surface of the hemisphere by a furrow, the *external rhinal fissure*, and is continuous behind with that part of the hemisphere, which will ultimately form the anterior end of the temporal lobe. The elevation becomes divided by a groove into an anterior and a posterior part. The anterior grows forward as a hollow stalk the lumen of which is continuous with the anterior part of the ventricular cavity. During the third month the stalk becomes solid and forms the rudiment of the olfactory bulb and tract; a strand of gelatinous tissue in the interior of the bulb indicates the position of the original cavity. From the posterior part the anterior perforated substance and the pyriform lobe are developed; at the beginning of the fourth month the latter forms a curved elevation continuous behind with the medial surface of the temporal lobe, and consisting, from before backward, of the *gyrus olfactorius lateralis*, *gyrus ambiens*, and *gyrus semilunaris*, parts which

Gyr. olf.
Gyr. olf. lat.

Gyr. ambiens
Gyr. diagonalis
Gyr. semilunaris

in the adult brain are represented by the lateral root of the olfactory tract and the uncus. The position and connections of the remaining portions of the rhinencephalon are described with the anatomy of the brain.

The **corpus striatum** (Figs. 126 and 128) appears in the fourth week as a triangular thickening of the floor of the telencephalon between the optic recess and the interventricular foramen, and continuous behind with the thalamic part of the diencephalon. It increases in size, and by the second month is seen as a swelling in the floor of the future lateral ventricle; this swelling reaches as far as the posterior end of the primitive hemisphere, and when this part of the hemisphere grows backward and downward to form the temporal lobe, the posterior part of the corpus striatum is carried into the roof of the inferior horn of the ventricle, where it is seen as the tail of the caudate nucleus in the adult brain. During the fourth and fifth months the corpus striatum becomes incompletely subdivided by the fibres of the internal capsule into two masses, an inner, the **caudate nucleus**, and an outer, the **lentiform nucleus**. In front, the corpus striatum is continuous with the anterior perforated substance; laterally it is confluent for a time with that portion of the wall of the vesicle which is developed into the insula, but this continuity is subsequently interrupted by the fibres of the external capsule.

Falx cerebri

Hippocampus fissure

Cs. Corpus striatum. Th. Thalamus.

FIG. 131.—Diagrammatic coronal section of brain to show relations of neopallium. (After His.) Cs. Corpus striatum. Th. Thalamus.

The **neopallium** (Fig. 131) forms the remaining, and by far the greater, part of the cerebral hemisphere. It consists, at an early stage, of a relatively large, more or less hemispherical cavity—the primitive **lateral ventricle**—enclosed by a thin wall from which the cortex of the hemisphere is developed. The vesicle expands in all directions, but more especially upward and backward, so that by the third month the hemispheres cover the diencephalon, by the sixth they overlap the mid-brain, and by the eighth the hind-brain.

The median lamina uniting the two hemispheres does not share in their expansion, and thus the hemispheres are separated by a deep cleft, the forerunner of the longitudinal fissure, and this cleft is occupied by a septum of mesodermal tissue which constitutes the primitive **falx cerebri**. Coincidentally with the expan-

sion of the vesicle, its cavity is drawn out into three prolongations which represent the horns of the future lateral ventricle; the hinder end of the vesicle is carried downward and forward and forms the inferior horn; the posterior horn is produced somewhat later, in association with the backward growth of the occipital lobe of the hemisphere. The roof-plate of the primitive fore-brain remains thin and of an epithelial character; it is invaginated into the lateral ventricle along the medial wall of the hemisphere. This invagination constitutes the choroidal fissure, and extends from the interventricular foramen to the posterior end of the vesicle. Mesodermal tissue, continuous with that of the primitive falx cerebri, and carrying bloodvessels with it, spreads between the two layers of the invaginated fold and forms the rudiment of the tela choroidea; the margins of the tela become highly vascular and form the choroid plexuses which for some months almost completely fill the ventricular cavities; the tela at the same time invaginates the epithelial roof of the diencephalon to form the choroid plexuses of the third ventricle. By the downward and forward growth of the posterior end of the vesicle to form the temporal lobe the choroidal fissure finally reaches from the interventricular foramen to the extremity of the inferior horn of the ventricle.

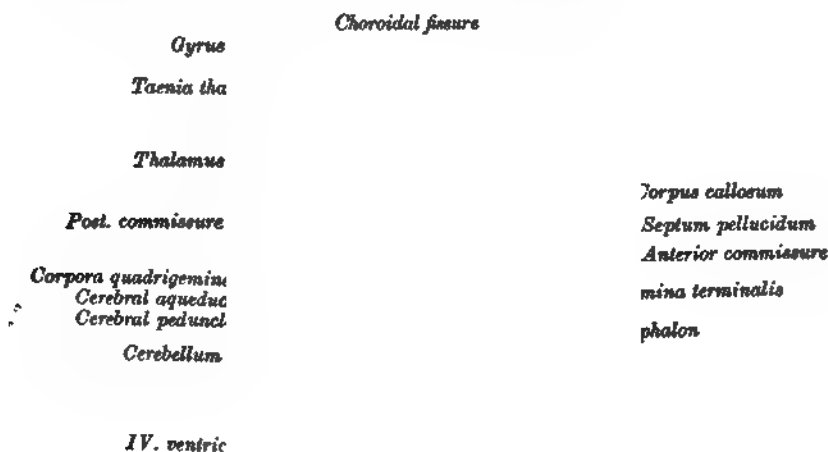

FIG. 132.—Median sagittal section of brain of human embryo of four months. (Marchand.)

Parallel with but above and in front of the choroidal fissure the medial wall of the cerebral vesicle becomes folded outward and gives rise to the **hippocampal fissure** on the medial surface and to a corresponding elevation, the **hippocampus**, within the ventricular cavity. The gray or ganglionic covering of the wall of the vesicle ends at the inferior margin of the fissure is a thickened edge; beneath this the marginal or reticular layer (future white substance) is exposed and its lower thinned edge is continuous with the epithelial invagination covering the choroid plexus (Fig. 131). As a result of the later downward and forward growth of the temporal lobe the hippocampal fissure and the parts associated with it extend from the interventricular foramen to the end of the inferior horn of the ventricle. The thickened edge of gray substance becomes the gyrus dentatus, the fasciola cinerea and the supra- and subcallosal gyri, while the free edge of the white substance forms the fimbria hippocampi and the body and crus of the fornix. The corpus callosum is developed within the arch of the hippocampal fissure, and the upper part of the fissure forms, in the adult brain, the callosal fissure on the medial surface of the hemisphere.

The Commissures (Fig. 132).—The development of the posterior commissure has already been referred to (page 127). The great commissures of the hemispheres, viz., the **corpus callosum**, the **fornix**, and **anterior commissure**, arise from the lamina terminalis. About the fourth month a small thickening appears in this lamina, immediately in front of the interventricular foramen. The lower part of this thickening is soon constricted off, and fibres appear in it to form the anterior commissure. The upper part continues to grow with the hemispheres, and is invaded by two sets of fibres. Transverse fibres, extending between the hemispheres, pass into its dorsal part, which is now differentiated as the corpus callosum (in rare cases the corpus callosum is not developed). Into the ventral part longitudinal fibres from the hippocampus pass to the lamina terminalis, and through that structure to the corpora mamillaria; these fibres constitute the fornix. A small portion, lying antero-inferiorly between the corpus callosum and fornix, is not invaded by the commissural fibres; it remains thin, and later a cavity, the cavity of the septum pellucidum, forms in its interior.

Fissures and Sulci.—The outer surface of the cerebral hemisphere is at first smooth, but later it exhibits a number of elevations or convolutions, separated from each other by fissures and sulci, most of which make their appearance during the sixth or seventh months of fetal life. The term *fissure* is applied to such grooves as involve the entire thickness of the cerebral wall, and thus produce corresponding eminences in the ventricular cavity, while the *sulci* affect only the superficial part of the wall, and therefore leave no impressions in the ventricle. The fissures comprise the **choroidal** and **hippocampal** already described, and two others, viz., the **calcarine** and **collateral**, which produce the swellings known respectively as the **calcar avis** and the **collateral eminence** in the ventricular cavity. Of the sulci the following may be referred to, viz., the **central sulcus** (*fissure of Rolando*), which is developed in two parts; the **intraparietal sulcus** in four parts; and the **cingulate sulcus** in two or three parts. The **lateral cerebral** or **Sylvian fissure** differs from all the other fissures in its mode of development. It appears about the third month as a depression, the **Sylvian fossa**, on the lateral surface of the hemisphere (Fig. 133); this fossa corresponds with the position of the corpus striatum, and its floor is moulded to form the insula. The intimate connection which exists between the cortex of the insula and the subjacent corpus striatum prevents this part of the hemisphere wall from expanding at the same rate as the portions which surround it. The neighboring parts of the hemisphere therefore gradually grow over and cover in the insula, and constitute the temporal, parietal, frontal, and orbital opercula of the adult brain. The frontal and orbital opercula are the last to form, but by the end of the first year after birth the insula is completely submerged by the approximation of the opercula. The fissures separating the opposed margins of the opercula constitute the composite lateral cerebral fissure.

If a section across the wall of the hemisphere about the sixth week be examined microscopically it will be found to consist of a thin marginal or reticular layer, a thick endymal layer, and a thin intervening mantle layer. Neuroblasts from the

*Parietal
operculum*

Frontal operculum

FIG. 133.—Outer surface of cerebral hemisphere of human embryo of about five months.

ependymal and mantle layers migrate into the deep part of the marginal layer and form the cells of the cerebral cortex. The nerve fibres which form the underlying white substance of the hemispheres consist at first of outgrowths from the cells of the corpora striata and thalami; later the fibres from the cells of the cortex are added. Medullation of these fibres begins about the time of birth and continues until puberty.

A summary of the parts derived from the brain vesicles is given in the following table:

Rhombencephalon or Hind-brain	1. Myelencephalon	Medulla oblongata Lower part of fourth ventricle.
	2. Metencephalon	Pons Cerebellum Intermediate part of fourth ventricle.
	3. Isthmus rhomb- encephali	Anterior medullary velum Brachia conjunctiva cerebelli. Upper part of fourth ventricle.
Mesencephalon or Mid-brain		Cerebral peduncles Lamina quadrigemina Cerebral aqueduct.
Prosencephalon or Fore-brain	1. Diencephalon	Thalamus Metathalamus Epithalamus Pars mamillaria hypo- thalami Posterior part of third ventricle.
	2. Telencephalon	Anterior part of third ventricle Pars optica hypo- thalami Cerebral hemispheres Lateral ventricles Interventricular foramen.

The Cerebral Nerves.—With the exception of the olfactory, optic, and acoustic nerves, which will be especially considered, the cerebral nerves are developed in a similar manner to the spinal nerves (see page 119). The sensory or afferent nerves are derived from the cells of the ganglion rudiments of the neural crest. The central processes of these cells grow into the brain and form the roots of the nerves, while the peripheral processes extend outward and constitute their fibres of distribution (Fig. 120). It has been seen, in considering the development of the medulla oblongata (page 123), that the *tractus solitarius* (Fig. 135), derived from the fibres which grow inward from the ganglion rudiments of the glossopharyngeal and vagus nerves, is the homologue of the **oval bundle** in the cord which had its origin in the posterior nerve roots. The motor or efferent nerves arise as outgrowths of the neuroblasts situated in the basal laminae of the mid- and hind-brain. While, however, the spinal motor nerve roots arise in one series from the basal lamina, the cerebral motor nerves are grouped into two sets, according as they spring from the medial or lateral parts of the basal lamina. To the former set belong the oculomotor, trochlear, abducent, and hypoglossal nerves; to the

latter, the accessory and the motor fibres of the trigeminal, facial, glossopharyngeal, vagus nerves (Figs. 134, 135).

The Sympathetic System.—The ganglion cells of the sympathetic system are derived from the cells of the neural crests. As these crests move forward along the sides of the neural tube and become segmented off to form the spinal ganglia, certain cells detach themselves from the ventral margins of the crests and migrate toward the sides of the aorta, where some of them are grouped to form the ganglia of the sympathetic trunks, while others undergo a further migration and form the ganglia of the prevertebral and visceral plexuses. The ciliary, sphenopalatine, otic, and submaxillary ganglia which are found on the branches of the trigeminal nerve are formed by groups of cells which have migrated from the part of the neural crest which gives rise to the semilunar ganglion. Some of the cells of the ciliary ganglion are said to migrate from the neural tube along the oculomotor nerve.

Chromaffin Organs.—The tissue from which the sympathetic ganglia are formed is at first a syncytium of cells termed sympatho-chromaffin cells, but later two kinds of cells become differentiated from it; the smaller cells (sympathoblasts) are transformed into the sympathetic nerve cells, the larger become chromaffin cells, and, separating from the others, accumulate to form the chromaffin organs.

FIG. 135.—Transverse section of medulla oblongata of human embryo. (After His.)

In the gangliated trunk of the sympathetic the chromaffin bodies are situated in depressions in the ganglia. In connection with certain, but not all, of the secondary plexuses of the sympathetic system chromaffin organs are found; the largest members of this series are the **aortic bodies**, which lie along the sides of the abdominal aorta between the superior mesenteric and common iliac arteries; to this group

belong also the **carotid sheaths**. After birth the chromaffin organs degenerate and can no longer be isolated by gross dissection, but chromaffin tissue can be recognized with the microscope in the sites originally occupied by them.

The Suprarenal Glands.—Each suprarenal gland consists of a cortical portion derived from the coelomic epithelium and a medullary portion originally composed of sympatho-chromaffin tissue. The cortical portion is first recognizable about

FIG. 136.—Transverse section of head of chick embryo of forty-eight hours' incubation. (Duval.)

the beginning of the fourth week as a series of buds from the coelomic cells at the root of the mesentery. Later it becomes completely separated from the coelomic epithelium and forms a suprarenal ridge projecting into the coelom between the mesonephros and the root of the mesentery. Into this cortical portion cells from the neighboring masses of sympatho-chromaffin tissue migrate along the line of its central vein to reach and form the medullary portion of the gland.

The Nose.—The development of the nose has already been considered (pages 111, 112).

The **olfactory nerves** are developed from the cells of the ectoderm which lines the olfactory pits; these cells undergo proliferation and give rise to what are termed the **olfactory cells** of the nose. The axons of the olfactory cells grow into the overlying olfactory bulb and form the olfactory nerves.

The Eye.—The eyes begin to develop as a pair of diverticula from the lateral aspects of the fore-brain. These diverticula make their appearance before the closure of the anterior end of the neural tube; after the closure of the tube they are

known as the **optic vesicles**. They project toward the sides of the head, and the peripheral part of each expands to form a hollow bulb, while the proximal part remains narrow and constitutes the **optic stalk** (Figs. 136, 137). The ectoderm overlying the bulb becomes thickened, invaginated, and finally severed from the ectodermal covering of the head as a vesicle of cells, the **lens vesicle**, which constitutes the rudiment of the crystalline lens. The outer wall of the bulb becomes thickened and invaginated, and the bulb is thus converted into a cup, the **optic cup**,

FIG. 137.—Transverse section of head of chick embryo of fifty-two hours' incubation. (Duval.)

consisting of two strata of cells (Fig. 137). These two strata are continuous with each other at the cup margin, which ultimately overlaps the front of the lens and reaches as far forward as the future aperture of the pupil. The invagination is not limited to the outer wall of the bulb, but involves also its postero-inferior surface and extends in the form of a groove for some distance along the optic stalk, so that, for a time, a gap or fissure, the *choroidal fissure*, exists in the lower part of the cup (Fig. 138). Through the groove and fissure the mesoderm extends into the optic stalk and cup, and in this mesoderm a bloodvessel is developed; during the seventh week the groove and fissure are closed and the vessel forms the central artery of the retina. Sometimes the choroidal fissure persists, and when this occurs the choroid and iris in the region of the fissure remain undeveloped, giving rise to the condition known as *coloboma* of the choroid or iris.

FIG. 138.—Optic cup and choroidal fissure seen from below, from a human embryo of about four weeks. (Kollmann.)

The *retina* is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells which assume a columnar shape, acquire pigment, and form the pigmented layer of the retina; the pigment first appears in the cells near the edge of the cup. The cells of the inner stratum proliferate and form a layer of considerable thickness from which the nervous elements and the sustentacular fibres of the retina, together with a portion of the vitreous body, are developed. In that portion of the cup which overlaps the lens the inner stratum is not differentiated into nervous elements, but forms a layer of columnar cells which is applied to the pigmented layer, and these two strata form the *pars ciliaris* and *pars iridica retinae*.

The cells of the inner or retinal layer of the optic cup become differentiated into spongioblasts and germinal cells, and the latter by their subdivisions give rise to neuroblasts. From the spongioblasts the sustentacular fibres of Müller, the outer and inner limiting membranes, together with the groundwork of the molecular layers of the retina are formed. The neuroblasts become arranged to form the ganglionic and nuclear layers. The layer of rods and cones is first developed in the central part of the optic cup, and from there gradually extends toward the cup margin. All the layers of the retina are completed by the eighth month of fetal life.

The optic stalk is converted into the *optic nerve* by the obliteration of its cavity and the growth of nerve fibres into it. Most of these fibres are centripetal, and grow backward into the optic stalk from the nerve cells of the retina, but a few extend in the opposite direction and are derived from nerve cells in the brain. The fibres of the optic nerve receive their medullary sheaths about the tenth week after

belong also the **carotid sheaths**. After birth the chromaffin organs degenerate and can no longer be isolated by gross dissection, but chromaffin tissue can be recognized with the microscope in the sites originally occupied by them.

The Suprarenal Glands.—Each suprarenal gland consists of a cortical portion derived from the coelomic epithelium and a medullary portion originally composed of sympatho-chromaffin tissue. The cortical portion is first recognizable about

FIG. 136.—Transverse section of head of chick embryo of forty-eight hours' incubation. (Duval)

the beginning of the fourth week as a series of buds from the coelomic cells at the root of the mesentery. Later it becomes completely separated from the coelomic epithelium and forms a suprarenal ridge projecting into the coelom between the mesonephros and the root of the mesentery. Into this cortical portion cells from the neighboring masses of sympatho-chromaffin tissue migrate along the line of its central vein to reach and form the medullary portion of the gland.

The Nose.—The development of the nose has already been considered (pages 111, 112).

The **olfactory nerves** are developed from the cells of the ectoderm which lines the olfactory pits; these cells undergo proliferation and give rise to what are termed the **olfactory cells** of the nose. The axons of the olfactory cells grow into the overlying olfactory bulb and form the olfactory nerves.

The Eye.—The eyes begin to develop as a pair of diverticula from the lateral aspects of the fore-brain. These diverticula make their appearance before the closure of the anterior end of the neural tube; after the closure of the tube they are

FIG. 137.—Transverse section of head of chick embryo of fifty-two hours' incubation. (Duval.)

known as the **optic vesicles**. They project toward the sides of the head, and the peripheral part of each expands to form a hollow bulb, while the proximal part remains narrow and constitutes the **optic stalk** (Figs. 136, 137). The ectoderm overlying the bulb becomes thickened, invaginated, and finally severed from the ectodermal covering of the head as a vesicle of cells, the **lens vesicle**, which constitutes the rudiment of the crystalline lens. The outer wall of the bulb becomes thickened and invaginated, and the bulb is thus converted into a cup, the **optic cup**,

consisting of two strata of cells (Fig. 137). These two strata are continuous with each other at the cup margin, which ultimately overlaps the front of the lens and reaches as far forward as the future aperture of the pupil. The invagination is not limited to the outer wall of the bulb, but involves also its postero-inferior surface and extends in the form of a groove for some distance along the optic stalk, so that, for a time, a gap or fissure, the **choroidal fissure**, exists in the lower part of the cup (Fig. 138). Through the groove and fissure the mesoderm extends into the optic stalk and cup, and in this mesoderm a bloodvessel is developed; during the seventh week the groove and fissure are closed and the vessel forms the central artery of the retina. Sometimes the choroidal fissure persists, and when this occurs the choroid and iris in the region of the fissure remain undeveloped, giving rise to the condition known as *coloboma* of the choroid or iris.

FIG. 138.—Optic cup and choroidal fissure seen from below, from a human embryo of about four weeks. (Kollmann.)

The **retina** is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells which assume a columnar shape, acquire pigment, and form the pigmented layer of the retina; the pigment first appears in the cells near the edge of the cup. The cells of the inner stratum proliferate and form a layer of considerable thickness from which the nervous elements and the sustentacular fibres of the retina, together with a portion of the vitreous body, are developed. In that portion of the cup which overlaps the lens the inner stratum is not differentiated into nervous elements, but forms a layer of columnar cells which is applied to the pigmented layer, and these two strata form the **pars ciliaris** and **pars iridica retinae**.

The cells of the inner or retinal layer of the optic cup become differentiated into spongioblasts and germinal cells, and the latter by their subdivisions give rise to neuroblasts. From the spongioblasts the sustentacular fibres of Müller, the outer and inner limiting membranes, together with the groundwork of the molecular layers of the retina are formed. The neuroblasts become arranged to form the ganglionic and nuclear layers. The layer of rods and cones is first developed in the central part of the optic cup, and from there gradually extends toward the cup margin. All the layers of the retina are completed by the eighth month of fetal life.

The optic stalk is converted into the **optic nerve** by the obliteration of its cavity and the growth of nerve fibres into it. Most of these fibres are centripetal, and grow backward into the optic stalk from the nerve cells of the retina, but a few extend in the opposite direction and are derived from nerve cells in the brain. The fibres of the optic nerve receive their medullary sheaths about the tenth week after

birth. The **optic chiasma** is formed by the meeting and partial decussation of the fibres of the two optic nerves. Behind the chiasma the fibres grow backward as the optic tracts to the thalami and mesencephalon.

The **crystalline lens** is developed from the lens vesicle, which recedes within the margin of the cup, and becomes separated from the overlying ectoderm by mesoderm. The cells forming the posterior wall of the vesicle lengthen and are converted into the lens fibres, which grow forward and fill up the cavity of the vesicle (Fig. 139). The cells forming the anterior wall retain their cellular character, and form the epithelium on the anterior surface of the adult lens. By the second month the lens is invested by a vascular mesodermal capsule, the **capsula vasculosa lentis**; the bloodvessels supplying the posterior part of this capsule are derived from the hyaloid artery; those for the anterior part from the anterior ciliary arteries; the portion of the capsule which covers the front of the lens is named the **pupillary**

Pars ciliaris and pars iridica retinae

FIG. 139.—Horizontal section through the eye of an eighteen days' embryo rabbit. $\times 30$. (KSHker.)

membrane. By the sixth month all the vessels of the capsule are atrophied except the hyaloid artery, which disappears during the ninth month; the position of this artery is indicated in the adult by the hyaloid canal, which reaches from the optic disk to the posterior surface of the lens. With the loss of its bloodvessels the **capsula vasculosa lentis** disappears, but sometimes the pupillary membrane persists at birth, giving rise to the condition termed *congenital atresia of the pupil*.

The **vitreous body** is developed between the lens and the optic cup. The lens rudiment and the optic vesicle are at first in contact with each other, but after the closure of the lens vesicle and the formation of the optic cup the former withdraws itself from the retinal layer of the cup; the two, however, remain connected by a network of delicate protoplasmic processes. This network, derived partly from the cells of the lens and partly from those of the retinal layer of the cup, constitutes the primitive vitreous body (Figs. 140, 141). At first these protoplasmic processes spring from the whole of the retinal layer of the cup, but later are limited to the

ciliary region, where by a process of condensation they appear to form the zonula ciliaris. The mesoderm which enters the cup through the choroidal fissure and around the equator of the lens becomes intimately united with this reticular tissue, and contributes to form the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm.

FIG. 140.—Sagittal section of eye of human embryo of six weeks. (Kollmann.)

The **anterior chamber** of the eye appears as a cleft in the mesoderm separating the lens from the overlying ectoderm. The layer of mesoderm in front of the cleft forms the substantia propria of the cornea, that behind the cleft the stroma of the iris and the pupillary membrane. The fibres of the ciliary muscle are derived from the mesoderm, but those of the Sphincter and Dilatator pupillae are of ectodermal origin, being developed from the cells of the pupillary part of the optic cup.

The **sclera** and **choroid** are derived from the mesoderm surrounding the optic cup.

The **eyelids** are formed as small cutaneous folds (Figs. 139, 140), which about the middle of the third month come together and unite in front of the cornea. They remain united until about the end of the sixth month.

The **lacrimal sac** and **nasolacrimal duct** result from a thickening of the ectoderm in the groove, **nasolacrimal furrows**, between the lateral nasal and maxillary processes. This thickening forms a solid cord of cells which sinks into the mesoderm; during the third month the central cells of the cord break down, and a lumen, the nasolacrimal duct, is established. The lacrimal ducts arise as buds from the upper part

of the cord of cells and secondarily establish openings (*puncta lacrimalia*) on the margins of the lids. The **epithelium** of the cornea and conjunctiva, and that which lines the ducts and alveoli of the lacrimal gland, are of ectodermal origin, as are also the **eyelashes** and the lining cells of the glands which open on the lid-margins.

FIG. 141.—Section of developing eye of trout. (Szily)

The Ear.—The first rudiment of the internal ear appears shortly after that of the eye, in the form of a patch of thickened ectoderm, the **auditory plate**, over the region of the hind-brain. The auditory plate becomes depressed and converted into the **auditory pit** (Fig. 142). The mouth of the pit is then closed, and thus a shut sac, the **auditory vesicle**, is formed (Fig. 143); from it the epithelial lining of the

FIG. 142. Section through the head of a human embryo, about twelve days old, in the region of the hind brain. (Kollmann.)

FIG. 143.—Section through hind brain and auditory vesicle of an embryo more advanced than that of Fig. 142 (After Hia.)

membranous labyrinth is derived. The vesicle becomes pear-shaped, and the neck of the flask is obliterated (Fig. 144). From the vesicle certain diverticula are given off which form the various parts of the membranous labyrinth. One from the middle part forms the ductus and saccus endolymphaticus, another from the anterior end gradually elongates, and, forming a tube coiled on itself, becomes the

cochlear duct, the vestibular extremity of which is subsequently constricted to form the canalis reuniens. Three others appear as disk-like evaginations on the surface of the vesicle; the central parts of the walls of the disks coalesce and disappear, while the peripheral portions persist to form the semicircular ducts; of these the

FIG. 144.—Left auditory vesicle of a human embryo of four weeks, seen from the outer surface. (W. His, Jr.)

Rudiment of cochlear duct

FIG. 145.—Left auditory vesicle of a human embryo of five weeks, seen from the outer surface. (W. His, Jr.)

superior is the first and the lateral the last to be completed (Figs. 145, 146). The central part of the vesicle represents the membranous vestibule, and is subdivided by a constriction into a smaller ventral part, the saccule, and a larger dorsal and posterior part, the utricle. This subdivision is effected by a fold which extends

FIG. 146.—Transverse section through head of fetal sheep, in the region of the labyrinth. X 30. (After Boettcher.)

deeply into the proximal part of the ductus endolymphaticus, with the result that the utricle and saccule ultimately communicate with each other by means of a Y-shaped canal. The saccule opens into the cochlear duct, through the canalis reuniens, and the semicircular ducts communicate with the utricle (Fig. 147).

The mesodermal tissue surrounding the various parts of the epithelial labyrinth is converted into a cartilaginous ear-capsule, and this is finally ossified to form the bony labyrinth. Between the cartilaginous capsule and the epithelial structures is a stratum of mesodermal tissue which is differentiated into three layers, viz.,

FIG. 147.—Left membranous labyrinth of a human embryo of 30 mm. (From model by W. His, Jr.)

an outer, forming the periosteal lining of the bony labyrinth; an inner, in direct contact with the epithelial structures; and an intermediate, consisting of gelatinous tissue: by the absorption of this latter tissue the perilymphatic spaces are developed. The modiolus and osseous spiral lamina of the cochlea are not preformed in cartilage but are ossified directly from connective tissue.

nerve utricle saccule embryonic

spirale

organ of Corti

FIG. 148.—Transverse section of the cochlear duct of a fetal cat. (After Boettcher and Ayres.)

The middle ear and auditory tube are developed from the first pharyngeal pouch. The entodermal lining of the dorsal end of this pouch is in contact with the ectoderm of the corresponding pharyngeal groove; by the extension of the mesoderm between these two layers the tympanic membrane is formed. During the sixth or

seventh month the tympanic antrum appears as an upward and backward expansion of the tympanic cavity. With regard to the exact mode of development of the ossicles of the middle ear there is some difference of opinion. The view generally held is that the *incus* and *malleus* are developed from the proximal end of the mandibular (Meckel's) cartilage (Fig. 105) and that the *stapes* is formed from the proximal end of the second arch. The malleus, with the exception of its anterior process, is ossified from a single centre which appears near the neck of the bone; the anterior process is ossified separately in membrane and joins the main part of the bone about the sixth month of fetal life. The incus is ossified from one centre which appears in the upper part of its long crus and ultimately extends into its lenticular process. The stapes first appears as a ring (*annulus stapedius*) encircling a small vessel, the stapedia artery, which subsequently undergoes atrophy; it is ossified from a single centre which appears in its base.

The **external acoustic meatus** is developed from the first branchial groove. The lower part of this groove extends inward as a funnel-shaped tube (primary meatus) from which the cartilaginous portion and a small part of the roof of the osseous portion of the meatus are developed. From the lower part of the funnel-shaped tube an epithelial lamina extends downward and inward along the inferior wall of the primitive tympanic cavity; by the splitting of this lamina the inner part of the meatus (secondary meatus) is produced, while the inner portion of the lamina forms the cutaneous stratum of the tympanic membrane. The **auricula** or **pinna** is developed by the gradual differentiation of six tubercles (Fig. 149) which appear around the margin of the first branchial groove. Two tubercles appear on the posterior edge of the mandibular arch; these represent the rudiments of the tragus and crus helix. Three are found on the hyoid arch, and indicate, from below upward, the lobule, antitragus, and antihelix. One arises above the groove, and grows downward behind the antitragus and antihelix; from it and its downward prolongation the upper part of the helix and the cauda helix are developed (Figs. 150, 151).

Some observers, however, maintain that the lowest tubercle on the hyoid arch becomes the antitragus, and that the lobule is developed later as an independent formation. The rudiment of the **acoustic nerve** appears about the end of the third week as a group of ganglion cells closely applied to the cephalic edge of the auditory vesicle. Whether these cells are derived from the ectoderm adjoining the auditory vesicle, or have migrated from the wall of the neural tube, is as yet uncertain. Each cell gives off a proximal fibre which passes into the neural tube, and a distal which is distributed to the epithelial cells of the auditory vesicle.

DEVELOPMENT OF THE VASCULAR SYSTEM

Bloodvessels first make their appearance in several scattered *vascular areas* (Fig. 152) which are developed simultaneously between the entoderm and the mesoderm of the yolk-sac, *i. e.*, outside the body of the embryo.¹ Here the cells become

¹ No definite statement can be made as to whether the earliest vessels are derived from the entoderm of the yolk-sac or from the mesoderm overlying it, the most recent view favors the entoderm as the original source of the blood corpuscles and endothelium of the vessels.

Eye

FIG. 149 — Tubercles from which the different parts of the auricula are developed. (His.) 1, 2. Tubercles on mandibular arch. 3. Tubercle above cleft. 3, c. Prolongation of 3 downward. 4, 5, 6. Tubercles on hyoid arch. a.v. Auditory vesicle

arranged into solid strands or cords which join to form a close-meshed network, the *area vasculosa*, which covers the whole yolk-sac. The peripheral cells of these

strands become flattened and joined to each other by their edges to form the endothelium of the walls of the primitive bloodvessels. Fluid collects within the strands

Helix

elix
helicia
agus

and converts them into tubes, and the more centrally situated cells of the cell-cords are thus pushed to the sides of the vessels and appear as masses of loosely arranged cells projecting toward the lumen of the tube. These masses are termed **blood islands** (Fig. 153); their cells are detached to form the blood corpuscles. The earliest blood-vessels, therefore, are formed at several separate centres; from the walls of these vessels buds grow out, become vascularized and converted into new vessels, and join with those of neighboring areas to form a close meshwork. It is uncertain whether the vessels within the body of the embryo are extensions from this network (His) or whether they are of new formation. Most observers agree, however, that, after the aortæ have appeared,

FIG. 151.—Auricula in a more advanced stage of development than those represented in Fig. 150.

no other independent vessels are laid down, *i. e.*, all new vessels are derived from preëxisting ones.

FIG. 152.—Section through vascular area to show differentiation of primitive vascular cells. Diagrammatic.

Mesoderm *Blood island*

of vessel *Entoderm*

FIG. 153.—Section through developing bloodvessel. Diagrammatic.

The red and the colorless corpuscles of the blood are all derived from the nucleated cells of the blood islands—**mesamœboid cells of Minot**—and the earliest blood corpuscles are thus all nucleated; they are also capable of subdivision and of

executing amœboid movements. Some of these cells acquire coloring matter (*hemoglobin*); their nuclei disintegrate and are expelled and the non-nucleated red corpuscles result. Other mesamœboid cells retain their nuclei; some remain in the blood as the leucocytes; others wander out into the tissues, particularly into the liver, lymphoid tissues, and marrow of the bones, where they form specialized masses from which the corpuscles of the blood are regenerated. From the mesamœboid cells five chief forms are derived: (1) erythrocytes, (2) lymphocytes, (3) finely granular or neutrophil leucocytes, (4) coarsely granular or eosinophil leucocytes, (5) degenerating or basophil leucocytes.

The first rudiment of the heart appears as a pair of tubular vessels which are developed in the splanchnopleure of the pericardial area (Fig. 154). These are named the **primitive aortæ**, and a direct continuity is soon established between them and the vessels of the yolk-sac. Each receives anteriorly a vein—the **vitelline vein**—from the yolk-sac, and is prolonged backward on the lateral aspect of the notochord under the name of the **dorsal aortæ**. The dorsal aortæ give branches to the yolk-sac, and are continued backward through the body-stalk as the umbilical arteries to the villi of the chorion.

Eternod¹ describes the circulation in an embryo which he estimated to be about thirteen days old (Fig. 155). The rudiment of the heart is situated immediately below the fore-gut and consists of a short stem. It gives off two vessels, the primitive aortæ, which run backward, one on either side of the notochord, and then pass into the body-stalk along which they are carried to the chorion. From the chorionic villi the blood is returned by a pair of umbilical veins which unite in the body-stalk

to form a single vessel and subsequently encircle the mouth of the yolk-sac and open into the heart. At the junction of the yolk-sac and body-stalk each vein is joined by a branch from the vascular plexus of the yolk-sac. From his observations it seems that, in the human embryo, the chorionic circulation is established before that on the yolk-sac.

layers of the pericardial area is reversed. Each primitive aorta now consists of a ventral and a dorsal part connected anteriorly by an arch (Fig. 156); these three parts are named respectively the anterior ventral aorta, the dorsal aorta, and the first cephalic arch. The vitelline veins which enter the embryo through the

anterior wall of the umbilical orifice are now continuous with the posterior ends of the anterior ventral aorta. With the formation of the tail-fold the posterior parts of the primitive aortæ are carried forward in a ventral direction to form the posterior ventral aortæ and primary caudal arches.¹ In the pericardial region the two primitive aortæ grow together, and fuse to form a single tubular heart (Fig. 157), the posterior end of which receives the two vitelline veins, while from its anterior end the two anterior ventral aortæ emerge.² The first cephalic arches pass through the mandibular arches, and behind them five additional pairs subsequently develop, so that altogether six pairs of aortic arches are formed; the fifth arches are very transitory vessels connecting the ventral aortæ with the dorsal ends of the sixth arches. By the rhythmical contraction of the tubular heart the blood is forced through the aortæ and bloodvessels of the vascular area, from which it is returned to the heart by the vitelline veins. This constitutes the **vitelline circulation** (Fig. 156), and by means of it nutriment is absorbed from the yolk vitellus.

The vitelline veins at first open separately into the posterior end of the tubular heart, but after a time their terminal portions fuse to form a single vessel. The vitelline veins ultimately drain the blood from the digestive tube, and are modified to form the portal vein. This is caused by the growth of the liver, which interrupts their direct continuity with the heart; and the blood returned by them circulates through the liver before reaching the heart.

With the atrophy of the yolk-sac the vitelline circulation diminishes and ultimately ceases, while an increasing amount of blood is carried through the umbilical arteries to the villi of the chorion. Subsequently, as the non-placental chorionic villi atrophy, their vessels disappear; and then the umbilical arteries convey the whole of their contents to the placenta, whence it is returned to the heart by the umbilical veins. In this manner the placental circulation is established, and by means of it nutritive materials are absorbed from, and waste products given up to, the maternal blood.

The umbilical veins, like the vitelline, undergo interruption in the developing liver, and the blood returned by them passes through this organ before reaching the heart. Ultimately the right umbilical vein shrivels up and disappears, as will be explained later (page 156).

During the occurrence of these changes great alterations take place in the primitive heart and bloodvessels.

Further Development of the Heart.—Between the endothelial lining and the outer wall of the heart there exists for a time an intricate trabecular network of mesodermal tissue from which, at a later stage, the musculi papillares, chordæ tendineæ, and trabeculae carneæ are developed. The simple tubular heart, already described, becomes elongated and bent on itself so as to form an S-shaped loop, the anterior part bending to the right and the posterior part to the left (Fig. 157). The intermediate portion arches transversely from left to right, and then turns sharply forward into the anterior part of the loop. Slight constrictions make their appearance in the tube and divide it from behind forward into five parts, viz.: (1) the **sinus venosus**; (2) the **primitive atrium**; (3) the **primitive ventricle**; (4) the **bulbus cordis**, and (5) the **truncus arteriosus** (Figs. 158, 159). The constriction between the atrium and ventricle constitutes the **atrial canal**, and indicates the site of the future atrioventricular valves.

The **sinus venosus** is at first situated in the septum transversum (a layer of mesoderm in which the liver and the central tendon of the Diaphragma are developed) behind the primitive atrium, and is formed by the union of the vitelline veins. The veins or ducts of Cuvier from the body of the embryo and the umbilical veins from the placenta subsequently open into it (Fig. 160). The sinus is at first

¹ Young and Robinson, *Journal of Anatomy and Physiology*, vol. xxxii.

² In most fishes and in the amphibia the heart originates as a single median tube.

place transversely, and opens by a median aperture into the primitive atrium. Soon, however, it assumes an oblique position, and becomes crescentic in form; its right half or horn increases more rapidly than the left, and the opening into the atrium now communicates with the right portion of the atrial cavity. The right horn and transverse portion of the sinus ultimately become incorporated with and form a part of the adult right atrium, the line of union between it and the auricula

being indicated in the interior of the atrium by a vertical crest, the *crista terminalis* of His. The left horn, which ultimately receives only the left duct of Cuvier, persists as the coronary sinus (Fig. 161). The vitelline and umbilical veins are soon replaced by a single vessel, the *inferior vena cava*, and the three veins (inferior vena cava and right and left Cuvierian ducts) open into the dorsal aspect of the atrium by a common slit-like aperture (Fig. 162). The upper part of this aperture represents the opening of the permanent superior vena cava, the lower that of the inferior

vena cava, and the intermediate part the orifice of the coronary sinus. The slit-like aperture lies obliquely, and is guarded by two halves, the *right* and *left venous valves*; above the opening these unite with each other and are continuous with a fold named the *septum spurium*; below the opening they fuse to form a triangular thickening—the *spina vestibuli*. The right venous valve is retained; a small septum, the *sinus septum*, grows from the posterior wall of the sinus venosus to fuse

with the valve and divide it into two parts—an upper, the valve of the inferior vena cava, and a lower, the valve of the coronary sinus (Fig. 165). The extreme

upper portion of the right venous valve, together with the septum spurium, form the crista terminalis already mentioned. The upper and middle thirds of the left

venous valve disappear; the lower third is continued into the spina vestibuli, and later fuses with the septum secundum of the atria and takes part in the formation of the limbus fossae ovalis.

Ventricle

FIG. 163.—Heart showing expansion of the atria. (Drawn from Ecker-Zeigler model.)

The atrial canal is at first a short straight tube connecting the atrial with the ventricular portion of the heart, but its growth is relatively slow, and it becomes overlapped by the atria and ventricles so that its position on the surface of the heart is indicated only by an annular constriction (Fig. 163). Its lumen is reduced to a transverse slit, and two thickenings appear, one on its dorsal and another on its

ventral wall. These thickenings, or **endocardial cushions** (Fig. 162) as they are termed, project into the canal, and, meeting in the middle line, unite to form the **septum intermedium** which divides the canal into two channels, the future right and left atrioventricular orifices.

The **primitive atrium** grows rapidly and partially encircles the **bulbus cordis**; the groove against which the **bulbus cordis** lies is the first indication of a division into right and left atria. The cavity of the primitive atrium becomes subdivided into right and left chambers by a septum, the **septum primum** (Fig. 162), which grows downward into the cavity. For a time the atria communicate with each other by an opening, the **ostium primum of Born**, below the free margin of the septum. This opening is closed by the union of the **septum primum** with the **septum intermedium**, and the communication between the atria is reestablished through an opening which is developed in the upper part of the **septum primum**; this opening is known as the **foramen ovale** (*ostium secundum of Born*) and persists until birth. A second septum, the **septum secundum** (Figs. 164, 165), semilunar in shape, grows downward from the upper wall of the atrium immediately to the right of the primary septum and foramen ovale. Shortly after birth it fuses with the primary septum, and by this means the foramen ovale is closed, but sometimes the fusion is incomplete and the upper part of the foramen remains patent. The **limbus fossae**

ovalis denotes the free margin of the **septum secundum**. Issuing from each lung is a pair of **pulmonary veins**; each pair unites to form a single vessel, and these in turn join in a common trunk which opens into the left atrium. Subsequently the common trunk and the two vessels forming it expand and form the vestibule or greater part of the atrium, the expansion reaching as far as the openings of the four vessels, so that in the adult all four veins open separately into the left atrium.

The **primitive ventricle** becomes divided by a septum, the **septum inferius** or **ventricular septum** (Figs. 162, 164, 165), which grows upward from the lower part of the ventricle, its position being indicated on the surface of the heart by a furrow. Its dorsal part increases more rapidly than its ventral portion, and fuses with the dorsal part of the **septum intermedium**. For a time an **interventricular foramen** exists above its ventral portion (Fig. 165), but this foramen is ultimately closed by the fusion of the **aortic septum** with the **ventricular septum**.

When the heart assumes its S-shaped form the **bulbus cordis** lies ventral to and in front of the primitive ventricle. The adjacent walls of the **bulbus cordis** and ventricle approximate, fuse, and finally disappear, and the **bulbus cordis** now

communicates freely with the right ventricle, while the junction of the bulbus with the truncus arteriosus is brought directly ventral to and applied to the atrial canal.

FIG. 166.—Diagrams to illustrate the transformation of the bulbus cordis. (Keith.) *Au.* Atrium. *B.* Bulbus cordis. *RV.* Right ventricle. *LV.* Left ventricle. *P.* Pulmonary artery.

By the upgrowth of the ventricular septum the bulbus cordis is in great measure separated from the left ventricle, but remains an integral part of the right ventricle, of which it forms the infundibulum (Fig. 166).

FIG. 167.—Diagrams to show the development of the septum of the aortic bulb and of the ventricles. (Born.)

The truncus arteriosus and bulbus cordis are divided by the aortic septum (Fig. 167). This makes its appearance in three portions. (1) Two distal ridge-like

FIG. 168.—Transverse sections through the aortic bulb to show the growth of the aortic septum. The lowest section is on the left, the highest on the right of the figure. (After His.)

thickenings project into the lumen of the tube; these increase in size, and ultimately meet and fuse to form a septum, which takes a spiral course toward the proximal

end of the truncus arteriosus. It divides the distal part of the truncus into two vessels, the aorta and pulmonary artery, which lie side by side above, but near the heart the pulmonary artery is in front of the aorta. (2) Four endocardial cushions appear in the proximal part of the truncus arteriosus in the region of the future semilunar valves; the manner in which these are related to the aortic septum is described below. (3) Two endocardial thickenings—anterior and posterior—develop in the bulbus cordis and unite to form a short septum; this joins above with the aortic septum and below with the ventricular septum. The septum grows down into the ventricle as an oblique partition, which ultimately blends with the ventricular septum in such a way as to bring the bulbus cordis into communication with the pulmonary artery, and through the latter with the sixth pair of aortic arches; while the left ventricle is brought into continuity with the aorta, which communicates with the remaining aortic arches.

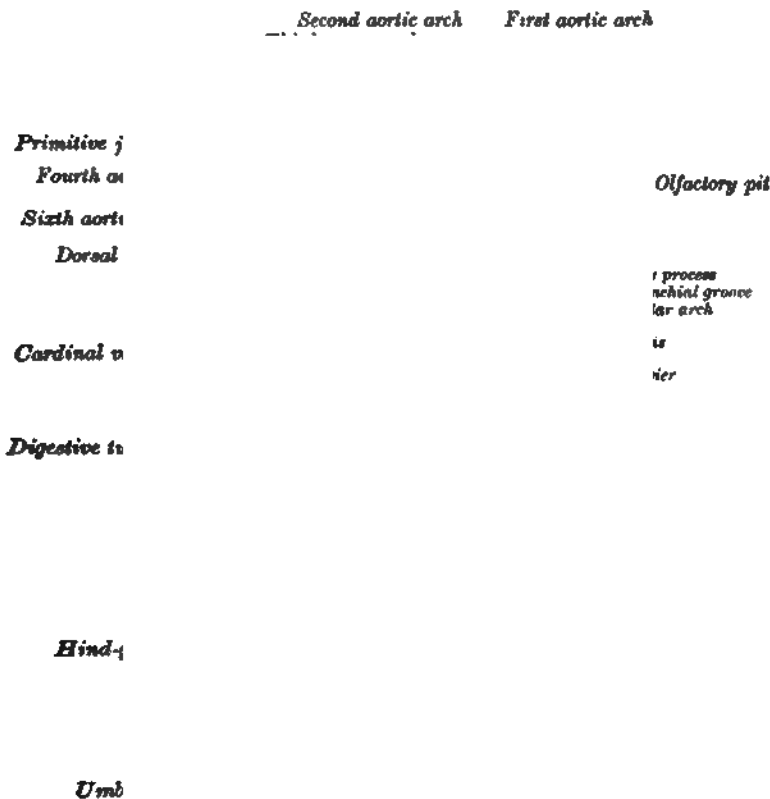

FIG. 160.—Profile view of a human embryo estimated at twenty or twenty-one days old. (After His.)

The Valves of the Heart.—The atrioventricular valves are developed in relation to the atrial canal. By the upward expansion of the bases of the ventricles the canal becomes invaginated into the ventricular cavities. The invaginated margin forms the rudiments of the lateral cusps of the atrioventricular valves; the mesial or septal cusps of the valves are developed as downward prolongations of the septum intermedium (Fig. 164). The aortic and pulmonary semilunar valves are formed from four endocardial thickenings—an anterior, a posterior, and two lateral—

which appear at the proximal end of the truncus arteriosus. As the aortic septum grows downward it divides each of the lateral thickenings into two, thus giving rise to six thickenings—the rudiments of the semilunar valves—three at the aortic and three at the pulmonary orifice (Fig. 168).

Further Development of the Arteries.—Recent observations show that practically none of the main vessels of the adult arise as such in the embryo. In the site of each vessel a capillary network forms, and by the enlargement of definite paths in this the larger arteries and veins are developed. The branches of the main arteries are not always simple modifications of the vessels of the capillary network, but may arise as new outgrowths from the enlarged stem.

FIG. 170.—Scheme of the aortic arches and their destination. (Modified from Kollmann.)

It has been seen (page 145) that each primitive aorta consists of a ventral and a dorsal part which are continuous through the first aortic arch. The dorsal aortæ at first run backward separately on either side of the notochord, but about the third week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single trunk, the descending aorta. The first aortic arches run through the mandibular arches, and behind them five additional pairs are developed within the visceral arches; so that, in all, six pairs of aortic arches are formed (Figs. 169, 170). The first and second arches pass between the ventral and dorsal aortæ, while the others arise at first by a common trunk from the truncus arteriosus, but end separately in the dorsal aortæ. As the neck elongates, the ventral aortæ are drawn out, and the third and fourth arches arise directly from these vessels.

In fishes these arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of them remain as permanent structures, while others disappear or become obliterated (Fig. 170).

The Anterior Ventral Aortæ.—These persist on both sides. The right forms (a) the innominate artery, (b) the right common and external carotid arteries. The left gives rise to (a) the short portion of the aortic arch, which reaches from the

origin of the innominate artery to that of the left common carotid artery; (b) the left common and external carotid arteries.

The Aortic Arches.—The first and second arches disappear early, but the dorsal end of the second gives origin to the stapedia artery (Fig. 171), a vessel which atrophies in man but persists in some mammals. It passes through the ring of the stapes and divides into supraorbital, infraorbital, and mandibular branches which follow the three divisions of the trigeminal nerve. The infraorbital and mandibular arise from a common stem, the terminal part of which anastomoses with

FIG. 171.—Diagram showing the origins of the main branches of the carotid arteries. (Founded on Tandler)

the external carotid. On the obliteration of the stapedia artery this anastomosis enlarges and forms the internal maxillary artery, and the branches of the stapedia artery are now branches of this vessel. The common stem of the infraorbital and mandibular branches passes between the two roots of the auriculotemporal nerve and becomes the middle meningeal artery; the original supraorbital branch of the stapedia is represented by the orbital twigs of the middle meningeal. The third aortic arch constitutes the commencement of the internal carotid artery, and is therefore named the carotid arch. The fourth right arch forms the right subclavian as far as the origin of its internal mammary branch; while the fourth left arch constitutes the arch of the aorta between the origin of the left carotid artery and the termination of the ductus arteriosus. The fifth arch disappears on both sides. The sixth right arch disappears; the sixth left arch gives off the pulmonary

arteries and forms the ductus arteriosus; this duct remains pervious during the whole of fetal life, but is obliterated a few days after birth. His showed that in the early embryo the right and left arches each gives a branch to the lungs, but that later both pulmonary arteries take origin from the left arch.

The Dorsal Aortæ.—In front of the third aortic arches the dorsal aortæ persist and form the continuations of the internal carotid arteries; these arteries pass to the brain and each divides into an anterior and a posterior branch, the former giving off the ophthalmic and the anterior and middle cerebral arteries, while the latter turns back and joins the cerebral part of the vertebral artery. Behind the third arch the right dorsal aorta disappears as far as the point where the two dorsal aortæ fuse to form the descending aorta. The part of the left dorsal aorta between the third and fourth arches disappears, while the remainder persists to form the descending part of the arch of the aorta. A constriction, the **aortic isthmus**, is sometimes seen in the aorta between the origin of the left subclavian and the attachment of the ductus arteriosus.

Sometimes the right subclavian artery arises from the aortic arch distal to the origin of the left subclavian and passes upward and to the right behind the trachea and œsophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth right arch.

In birds the fourth right arch forms the arch of the aorta; in reptiles the fourth arch on both sides persists and gives rise to the double aortic arch in these animals.

The heart originally lies on the ventral aspect of the pharynx, immediately behind the stomodeum. With the elongations of the neck and the development of the lungs it recedes within the thorax, and, as a consequence, the anterior ventral aortæ are drawn out and the original position of the fourth and fifth arches is greatly modified. Thus, on the right side the fourth recedes to the root of the neck, while on the left side it is withdrawn within the thorax. The recurrent nerves originally pass to the larynx under the sixth pair of arches, and are therefore pulled backward with the descent of these structures, so that in the adult the left nerve hooks around the ligamentum arteriosum; owing to the disappearance of the fifth and the sixth right arches the right nerve hooks around that immediately above them, *i.e.*, the commencement of the subclavian artery. Segmental arteries arise from the primitive dorsal aortæ and course between successive segments. The seventh segmental artery is of special interest, since it forms the lower end of the vertebral artery and, when the forelimb bud appears, sends a branch to it (the subclavian artery). From the seventh segmental arteries the entire left subclavian and the greater part of the right subclavian are formed. The second pair of segmental arteries accompany the hypoglossal nerves to the brain and are named the hypoglossal arteries. Each sends forward a branch which forms the cerebral part of the vertebral artery and anastomoses with the posterior branch of the internal carotid. The two vertebrals unite on the ventral surface of the hind-brain to form the basilar artery. Later the hypoglossal artery atrophies and the vertebral is connected with the first segmental artery. The cervical part of the vertebral is developed from a longitudinal anastomosis between the first seven segmental arteries, so that the seventh of these ultimately becomes the source of the artery. As a result of the growth of the upper limb the subclavian artery increases greatly in size and the vertebral then appears to spring from it.

Recent observations show that several segmental arteries contribute branches to the upper limb-bud and form in it a free capillary anastomosis. Of these branches, only one, *viz.*, that derived from the seventh segmental artery, persists to form the subclavian artery. The subclavian artery is prolonged into the limb under the names of the axillary and brachial arteries, and these together constitute the arterial stem for the upper arm, the direct continuation of this stem in the forearm is the volar interosseous artery. A branch which accompanies the median nerve

soon increases in size and forms the main vessel (median artery) of the forearm, while the volar interosseous diminishes. Later the radial and ulnar arteries are developed as branches of the brachial part of the stem and coincidently with their enlargement the median artery recedes; occasionally it persists as a vessel of some considerable size and then accompanies the median nerve into the palm of the hand.

The primary arterial stem for the lower limb is formed by the inferior gluteal (sciatic) artery, which accompanies the sciatic nerve along the posterior aspect of the thigh to the back of the knee, whence it is continued as the peroneal artery. This arrangement exists in reptiles and amphibians. The femoral artery arises later as a branch of the common iliac, and, passing down the front and medial side of the thigh to the bend of the knee, joins the inferior gluteal artery. The femoral quickly enlarges, and, coincidently with this, the part of the inferior gluteal immediately above the knee undergoes atrophy. The anterior and posterior tibial arteries are branches of the main arterial stem.

FIG. 172.—The liver and the veins in connection with it, of a human embryo, twenty-four or twenty-five days old; as seen from the ventral surface. (After His.)

Further Development of the Veins.—The formation of the great veins of the embryo may be best considered by dividing them into two groups, **visceral** and **parietal**.

The Visceral Veins.—The visceral veins are the two **vitelline** or **omphalomesenteric veins** bringing the blood from the yolk-sac, and the two **umbilical veins** returning the blood from the placenta; these four veins open close together into the sinus venosus.

The **Vitelline Veins** run upward at first in front, and subsequently on either side of the intestinal canal. They unite on the ventral aspect of the canal, and beyond this are connected to one another by two anastomotic branches, one on the dorsal, and the other on the ventral aspect of the duodenal portion of the intestine, which is thus encircled by two venous rings (Fig. 172); into the middle or dorsal anastomosis the superior mesenteric vein opens. The portions of the veins above the upper ring become interrupted by the developing liver and broken up by it into a plexus of small capillary-like vessels termed **sinusoids** (Minot). The branches conveying the blood to this plexus are named the **venae advehentes**, and become

the branches of the portal vein; while the vessels draining the plexus into the sinus venosus are termed the *venae revehentes*, and form the future hepatic veins (Figs. 172, 173). Ultimately the left vena revehens no longer communicates directly with the sinus venosus, but opens into the right vena revehens. The persistent part of the upper venous ring, above the opening of the superior mesenteric vein, forms the trunk of the portal vein.

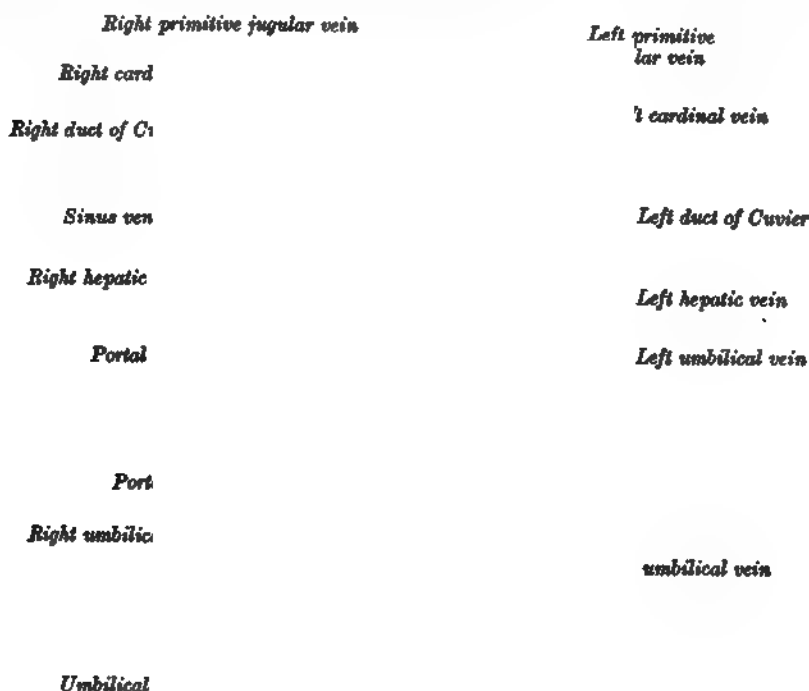

FIG. 173.—Human embryo with heart and anterior body-wall removed to show the sinus venosus and its tributaries. (After His.)

The two **Umbilical Veins** fuse early to form a single trunk in the body-stalk, but remain separate within the embryo and pass forward to the sinus venosus in the side walls of the body. Like the vitelline veins, their direct connection with the sinus venosus becomes interrupted by the developing liver, and thus at this stage the whole of the blood from the yolk-sac and placenta passes through the substance of the liver before it reaches the heart. The right umbilical and right vitelline veins shrivel and disappear; the left umbilical, on the other hand, becomes enlarged and opens into the upper venous ring of the vitelline veins; with the atrophy of the yolk-sac the left vitelline vein also undergoes atrophy and disappears. Finally a direct branch is established between this ring and the right hepatic vein; this branch is named the **ductus venosus**, and, enlarging rapidly, it forms a wide channel through which most of the blood, returned from the placenta, is carried direct to the heart without passing through the liver. A small proportion of the blood from the placenta is, however, conveyed from the left umbilical vein to the liver through the left vena advehens. The left umbilical vein and the ductus venosus undergo atrophy and obliteration after birth, and form respectively the ligamentum teres and ligamentum venosum of the liver.

The Parietal Veins.—The first indication of a parietal system consists in the appearance of two short transverse veins, the **ducts of Cuvier**, which open, one on either side, into the sinus venosus. Each of these ducts receives an ascending and descending vein. The ascending veins return the blood from the parietes of the trunk and from the Wolffian bodies, and are called **cardinal veins**. The descending veins return the blood from the head, and are called **primitive jugular veins** (Fig. 174). The blood from the lower limbs is collected by the right and left iliac and hypogastric veins, which, in the earlier stages of development, open into the corresponding right and left cardinal veins; later, a transverse branch (the left common iliac vein) is developed between the lower parts of the two cardinal veins (Fig. 176), and through this the blood is carried into the right cardinal vein. The portion of the left cardinal vein below the left renal vein atrophies and disappears up to the point of entrance of the left spermatic vein; the portion above the left renal vein persists as the hemiazygos and accessory hemiazygos veins and the lower portion of the highest left intercostal vein. The right cardinal vein

FIG. 174.—Scheme of arrangement of parietal veins.

FIG. 175.—Scheme showing early stages of development of the inferior vena cava.

which now receives the blood from both lower extremities, forms a large venous trunk along the posterior abdominal wall; up to the level of the renal veins it forms the lower part of the inferior vena cava. Above the level of the renal veins the right cardinal vein persists as the azygos vein and receives the right intercostal veins, while the hemiazygos veins are brought into communication with it by the development of transverse branches in front of the vertebral column (Figs. 176, 177)

Inferior Vena Cava.—The development of the inferior vena cava is associated with the formation of two veins, the **subcardinal veins** (Figs. 174, 175). These lie parallel to, and on the ventral aspect of, the cardinal veins, and originate as longitudinal anastomosing channels which link up the tributaries from the mesentery to the cardinal veins; they communicate with the cardinal veins above and below, and also by a series of transverse branches. The two subcardinals are for a time connected with each other in front of the aorta by cross branches, but these disappear and are replaced by a single transverse channel at the level where the renal veins join the cardinals, and at the same level a cross communication is

established on either side between the cardinal and subcardinal (Fig. 175). The portion of the right subcardinal behind this cross communication disappears, while that in front, *i. e.*, the prerenal part, forms a connection with the ductus venosus

FIG. 176.—Diagram showing development of main cross branches between jugulars and between cardinals.

at the point of opening of the hepatic veins, and, rapidly enlarging, receives the blood from the postrenal part of the right cardinal through the cross communica-

FIG. 177.—Diagram showing completion of development of the parietal veins.

tion referred to. In this manner a single trunk, the **inferior vena cava** (Fig. 177), is formed, and consists of the proximal part of the ductus venosus, the prerenal part of the right subcardinal vein, the postrenal part of the right cardinal vein, and the

cross branch which joins these two veins. The left subcardinal disappears, except the part immediately in front of the renal vein, which is retained as the left supra-renal vein. The spermatic (or ovarian) vein opens into the postrenal part of the corresponding cardinal vein. This portion of the right cardinal, as already explained, forms the lower part of the inferior vena cava, so that the right spermatic opens directly into that vessel. The postrenal segment of the left cardinal disappears, with the exception of the portion between the spermatic and renal vein, which is retained as the terminal part of the left spermatic vein.

In consequence of the atrophy of the Wolffian bodies the cardinal veins diminish in size; the primitive jugular veins, on the other hand, become enlarged, owing to the rapid development of the head and brain. They are further augmented by receiving the veins (subclavian) from the upper extremities, and so come to form

the chief veins of the Cuvierian ducts; these ducts gradually assume an almost vertical position in consequence of the descent of the heart into the thorax. The right and left Cuvierian ducts are originally of the same diameter, and are frequently termed the right and left superior *venæ cavæ*. By the development of a transverse branch, the left innominate vein between the two primitive jugular veins, the blood is carried across from the left to the right primitive jugular (Figs. 176, 177). The portion of the right primitive jugular vein between the left innominate and the azygos vein forms the upper part of the superior vena cava of the adult; the lower part of this vessel, *i. e.*, below the entrance of the azygos vein, is formed by the right Cuvierian duct. Below the origin of the transverse branch the left

FIG. 178.—Diagram of veins of head of an embryo four weeks old. (After Mall.)

FIG. 179.—Diagram of veins of head of an embryo five weeks old. (After Mall.)

primitive jugular vein and left Cuvierian duct atrophy, the former constituting the upper part of the highest left intercostal vein, while the latter is represented by the ligament of the left vena cava, vestigial fold of Marshall, and the oblique vein of the left atrium, oblique vein of Marshall (Fig. 177). Both right and left superior *venæ cavæ* are present in some animals, and are occasionally found in the adult human being. The oblique vein of the left atrium passes downward across the back of the left atrium to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus.

The primitive jugular veins drain the blood from the brain, and their proximal parts form the internal jugular veins. The distal portion of each has been named the *vena capitis medialis* (Fig. 178); it runs on the medial side of the auditory

vesicle and cerebral nerve roots, and the portion of it situated in the neighborhood of the trigeminal nerve becomes the cavernous sinus. The greater part of the *vena capitis medialis* is replaced, however, by the *vena capitis lateralis* (Fig. 179), which is developed on the lateral aspect of the cerebral nerves from the trigeminal to the hypoglossal. This vein receives three principal tributaries, viz., the anterior cerebral vein from the eye, fore-brain, and mid-brain, the middle cerebral vein

FIG. 180.—Diagram of veins of head at the beginning of the third month. (After Mall.)

from the cerebellum, and the posterior cerebral vein from the lower part of the hind-brain. At this stage, therefore, practically the whole of the blood from the brain is drained into the *vena capitis lateralis*, which leaves the skull in company with the facial nerve and opens into the internal jugular vein. The terminal branches of the two anterior cerebral veins anastomose in the middle line and thus form the

FIG. 181.—Diagram of veins of head of an older embryo. (After Mall.)

superior sagittal sinus (Fig. 180). By the backward growth of the cerebral hemispheres this sinus comes to anastomose with the middle and posterior cerebral veins, the latter of which leaves the skull through the jugular foramen; this last anastomosis forms the greater part of the transverse sinus. The *vena capitis lateralis* undergoes atrophy; the middle cerebral vein forms the superior petrosal sinus (Fig. 181). The inferior petrosal sinus is a later formation. The external jugular vein

at first drains the region behind the ear (posterior auricular) and enters the primitive jugular as a lateral tributary. A group of veins from the face and lingual region converge to form a common vein, the *linguo-facial*,¹ which also terminates in the primitive jugular. Later, cross communications develop between the external jugular and the *linguo-facial*, with the result that the posterior group of facial veins is transferred to the external jugular.

Peculiarities of the Fetal Heart.—In early fetal life the heart is placed directly under the head and is relatively of large size. Later it assumes its position in the thorax, but lies at first in the middle line; toward the end of pregnancy it gradually becomes oblique in direction. The atrial portion is at first larger than the ventricular part, and the two atria communicate freely through the *foramen ovale*. In consequence of the communication through the *ductus arteriosus*, between the pulmonary artery and the aorta, the contents of the right ventricle are mainly carried into the latter vessel instead of to the lungs, and hence the wall of the right ventricle is as thick as that of the left. At the end of fetal life, however, the left ventricle is thicker than the right, a difference which becomes more and more emphasized after birth.

The fetal circulation and the changes which take place in the circulation after birth are described on pages 616 to 618.

FIG. 182.—Scheme showing relative positions of primary lymph sacs based on the description given by Florence Sabin.

The Lymphatic Vessels.—The lymphatic system begins as a series of sacs² at the points of junction of certain of the embryonic veins. These lymph-sacs are developed by the confluence of numerous venous capillaries, which at first lose their connections with the venous system, but subsequently, on the formation of the sacs, regain them. The lymphatic system is therefore developmentally an offshoot of the venous system, and the lining walls of its vessels are always endothelial.

In the human embryo the lymph sacs from which the lymphatic vessels are derived are six in number; two paired, the jugular and the posterior lymph-sacs; and two unpaired, the retroperitoneal and the *cisterna chyli*. In lower mammals

¹ Lewis, *American Journal of Anatomy*, February, 1909, No. 1, vol. ix.

² Sabin, *ibid*.

an additional pair, subclavian, is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows: (1) jugular sac, the first to appear, at the junction of the subclavian vein with the primitive jugular; (2) posterior sac, at the junction of the iliac vein with the cardinal; (3) retroperitoneal, in the root of the mesentery near the suprarenal glands; (4) cisterna chyli, opposite the third and fourth lumbar vertebræ (Fig. 182). From the lymph-sacs the lymphatic vessels bud out along fixed lines corresponding more or less closely to the course of the embryonic bloodvessels. Both in the body-wall and in the wall of the intestine,¹ the deeper plexuses are the first to be developed; by continued growth of these the vessels in the superficial layers are gradually formed. The thoracic duct is probably formed from anastomosing outgrowths from the jugular sac and cisterna chyli. At its connection with the cisterna chyli it is at first double, but the two vessels soon join.

All the lymph-sacs except the cisterna chyli are, at a later stage, divided up by slender connective tissue bridges and transformed into groups of lymph glands. The lower portion of the cisterna chyli is similarly converted, but its upper portion remains² as the adult cisterna.

FIG. 183.—Diagram of a sagittal section of a mammalian embryo. Very early. (After Quain.)

DEVELOPMENT OF THE DIGESTIVE AND RESPIRATORY APPARATUS.

The Digestive Tube.—As already indicated (page 92), the primitive digestive tube consists of two parts, viz.: (1) the **fore-gut**, within the cephalic flexure, and dorsal to the heart; and (2) the **hind-gut**, within the caudal flexure (Figs. 183, 184). Between these is the wide opening of the yolk-sac, which is gradually narrowed and reduced to a small foramen leading into the vitelline duct. At first the fore-gut and hind-gut end blindly. The anterior end of the fore-gut is separated from

¹ Heuer, *American Journal of Anatomy*, vol. ix, No. 1, February, 1909.

the stomodeum by the buccopharyngeal membrane (Fig. 184); the hind-gut ends in the cloaca, which is closed by the cloacal membrane.

The Mouth.—The mouth is developed partly from the stomodeum, and partly from the floor of the anterior portion of the fore-gut. By the growth of the head end of the embryo, and the formation of the cephalic flexure, the pericardial area and the buccopharyngeal membrane come to lie on the ventral surface of the embryo. With the further expansion of the brain, and the forward bulging of the pericardium, the buccopharyngeal membrane is depressed between these two prominences. This depression constitutes the *stomodeum* (Fig. 184). It is lined by ectoderm, and is separated from the anterior end of the fore-gut by the buccopharyngeal membrane. This membrane is devoid of mesoderm, being formed by the apposition of the stomodeal ectoderm with the fore-gut entoderm; at the end of the third week it disappears, and thus a communication is established

FIG. 184.—Human embryo about fifteen days old. Brain and heart represented from right side. Digestive tube and yolk sac in median section. (After His.)

between the mouth and the future pharynx. No trace of the membrane is found in the adult; and the communication just mentioned must not be confused with the permanent isthmus faucium. The lips, teeth, and gums are formed from the walls of the stomodeum, but the tongue is developed in the floor of the pharynx.

The visceral arches extend in a ventral direction between the stomodeum and the pericardium; and with the completion of the mandibular arch and the formation of the maxillary processes, the mouth assumes the appearance of a pentagonal orifice. The orifice is bounded in front by the fronto-nasal process, behind by the mandibular arch, and laterally by the maxillary processes (Fig. 185). With the inward growth and fusion of the palatine processes (Figs. 112, 113), the stomodeum is divided into an upper nasal, and a lower buccal part. Along the free margins of the processes bounding the mouth cavity a shallow groove appears; this is termed the *primary labial groove*, and from the bottom of it a downgrowth of

ectoderm takes place into the underlying mesoderm. The central cells of the ectodermal downgrowth degenerate and a **secondary labial groove** is formed; by the deepening of this, the lips and cheeks are separated from the alveolar processes of the maxillæ and mandible.

The Salivary Glands.—The salivary glands arise as buds from the epithelial lining of the mouth; the parotid appears during the fourth week in the angle between the maxillary process and the mandibular arch; the submaxillary appears in the sixth week, and the sublingual during the ninth week in the hollow between the tongue and the mandibular arch.

The Tongue (Figs. 186 to 188).—The tongue is developed in the floor of the pharynx, and consists of an anterior or buccal and a posterior or pharyngeal part which are separated in the adult by the V-shaped sulcus terminalis. During the third week there appears, immediately behind the ventral ends of the two halves of the mandibular arch, a rounded swelling named the **tuberculum impar**, which was described by His as undergoing enlargement to form the buccal part of the tongue. More recent researches, however, show that this part of the tongue is mainly, if not entirely, developed from a pair of lateral swellings which rise from

FIG. 185.—Head end of human embryo of about thirty to thirty-one days. (From model by Peter.)

the inner surface of the mandibular arch and meet in the middle line. The tuberculum impar is said to form the central part of the tongue immediately in front of the foramen cecum, but Hammar insists that it is purely a transitory structure and forms no part of the adult tongue. From the ventral ends of the fourth arch

FIG. 186.—Floor of pharynx of human embryo about twenty-six days old. (From model by Peter.)

FIG. 187.—Floor of pharynx of human embryo of about the end of the fourth week. (From model by Peter.)

there arises a second and larger elevation, in the centre of which is a median groove or furrow. This elevation was named by His the **furcula**, and is at first separated from the tuberculum impar by a depression, but later by a ridge, the **copula**, formed by the forward growth and fusion of the ventral ends of the second and third arches. The posterior or pharyngeal part of the tongue is developed from

the copula, which extends forward in the form of a V, so as to embrace between its two limbs the buccal part of the tongue. At the apex of the V a pit-like invagination occurs, to form the thyroid gland, and this depression is represented in the adult by the **foramen cecum** of the tongue. In the adult the union of the anterior and posterior parts of the tongue is marked by the V-shaped sulcus terminalis, the apex of which is at the foramen cecum, while the two limbs run lateralward and forward, parallel to, but a little behind, the vallate papillæ.

The Thyroid Gland.—The thyroid gland is developed from a median diverticulum (Fig. 189), which appears about the fourth week on the summit of the tuberculum impar, but later is found in the furrow immediately behind the tuberculum (Fig. 186). It grows downward and backward as a tubular duct, which bifurcates and subsequently subdivides into a series of cellular cords, from which the isthmus and lateral lobes of the thyroid gland are developed. As already stated (page 111), the ultimobranchial bodies from the fifth pharyngeal pouches are enveloped by the lateral lobes of the thyroid gland; they undergo atrophy and do not form true thyroid tissue. The connection of the diverticulum with the pharynx is termed the **thyroglossal duct**; its continuity is subsequently interrupted, and it undergoes degeneration, its upper end being represented by the foramen cecum of the tongue, and its lower by the pyramidal lobe of the thyroid gland.

FIG. 188.—Floor of pharynx of human embryo about thirty days old. (From model by Peter.)

FIG. 189.—Scheme showing development of branchial epithelial bodies. (Modified from Kohn.) I, II, III, IV. Branchial pouches.

The Palatine Tonsils.—The palatine tonsils are developed from the dorsal angles of the second branchial pouches. The entoderm which lines these pouches grows in the form of a number of solid buds into the surrounding mesoderm. These buds become hollowed out by the degeneration and casting off of their central cells, and by this means the tonsillar crypts are formed. Lymphoid cells accumulate around the crypts, and become grouped to form the lymphoid follicles; the latter, however, are not well-defined until after birth.

The Thymus.—The thymus appears in the form of two flask-shaped entodermal diverticula, which arise, one on either side, from the third branchial pouch (Fig. 189), and extend lateralward and backward into the surrounding mesoderm in front of the ventral aortæ. Here they meet and become joined to one another by connective tissue, but there is never any fusion of the thymus tissue proper. The pharyngeal opening of each diverticulum is soon obliterated, but the neck of the flask persists for some time as a cellular cord. By further proliferation of the cells lining the flask, buds of cells are formed, which become surrounded and isolated

by the invading mesoderm. In the latter, numerous lymphoid cells make their appearance, and are aggregated to form lymphoid follicles. These lymphoid cells are probably derivatives of the entodermal cells which lined the original diverticula and their subdivisions. Additional portions of thymus tissue are sometimes developed from the fourth branchial pouches. Thymus continues to grow until the time of puberty and then begins to atrophy.

The Parathyroid Bodies.—The parathyroid bodies are developed as outgrowths from the third and fourth branchial pouches (Fig. 189).

A pair of diverticula arise from the fifth branchial pouch and form what are termed the **ultimobranchial bodies** (Fig. 189); these fuse with the thyroid gland, but probably contribute no true thyroid tissue.

The Hypophysis Cerebri.—

This in the adult consists of a large anterior, and a small posterior, lobe: the former is derived from the ectoderm of the stomodeum, the latter from the floor of the fore-brain. About the fourth week there appears a pouch-like diverticulum of the ectodermal lining of the roof of the stomodeum. This diverticulum, **pouch of Rathke** (Fig. 190), is the rudiment of the anterior lobe of the hypophysis; it extends upward in front of the cephalic end of the notochord and the remnant of the buccopharyngeal membrane and comes into contact with the under surface of the fore-brain. It is then constricted off to form a closed vesicle, but remains for a time connected to the ectoderm of the stomodeum by a solid cord of cells. Masses of epithelial cells form on either side and in the front

In *B* it is in the process of disappearing, and the stomodeum now communicates with the primitive pharynx. *am*, Amnion, *c*, Fore-brain, *ch*, Notochord, *f*, Anterior extremity of fore-gut, *h*, Heart, *if*, Infundibulum, *m*, Wall of brain cavity, *mc*, Mid-brain, *mo*, Hind-brain, *p*, Original position of hypophyseal diverticulum, *py*, *ph*, Pharynx, *sp.e*, Sphenothmoidal, *bc*, Central, *sp.o*, Sphenoccipital parts of basis cranii, *th*, Thalamus.

wall of the vesicle, and by the growth between these of a stroma from the mesoderm the development of the anterior lobe is completed. The upwardly directed hypophyseal involution becomes applied to the antero-lateral aspect of a downwardly directed diverticulum from the base of the fore-brain (page 128). This diverticulum constitutes the future infundibulum in the floor of the third ventricle while its inferior extremity becomes modified to form the posterior lobe of the hypophysis. In some of the lower animals the posterior lobe contains nerve cells and nerve fibres, but in man and the higher vertebrates these are replaced by connective tissue. A canal, **craniopharyngeal canal**, is sometimes found extending

from the anterior part of the fossa hypophyseos of the sphenoid bone to the under surface of the skull, and marks the original position of Rathke's pouch; while at

the junction of the septum of the nose with the palate traces of the stomodeal end are occasionally present (Frazer).

The Further Development of the Digestive Tube.—The upper part of the fore-gut becomes dilated to form the pharynx (Fig. 184), in relation to which the branchial arches are developed (see page 108); the succeeding part remains tubular, and with the descent of the stomach is elongated to form the oesophagus. About the fourth week a fusiform dilatation, the future stomach, makes its appearance, and beyond this the gut opens freely into the yolk-sac (Fig. 191, *A* and *B*). The opening is at first wide, but is gradually narrowed into a tubular stalk, the **yolk-stalk** or **vitelline duct**. Between the stomach and the mouth of the yolk-sac the liver diverticulum appears. From the stomach to the rectum the alimentary canal is attached to the notochord by a band of mesoderm, from which the common mesentery of the gut is subsequently developed. The stomach has an additional attachment, viz., to the ventral abdominal wall as far as the umbilicus by the septum transversum. The cephalic portion of the septum takes part in the formation of the Diaphragma, while the caudal portion into which the liver grows forms the **ventral mesogastrium** (Fig. 193). The stomach undergoes a further dilatation, and its two curvatures can be recognized (Figs. 191, *B*, and 192), the greater directed toward the vertebral

FIG. 192.—Front view of two successive stages in the development of the digestive tube. (His.)

column and the lesser toward the anterior wall of the abdomen, while its two surfaces look to the right and left respectively. Behind the stomach the gut undergoes great elongation, and forms a V-shaped loop which projects downward and forward; from the bend or angle of the loop the vitelline duct passes to the umbilicus (Fig. 193). For a time a considerable part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month it is withdrawn within the cavity. With the lengthening of the tube, the mesoderm, which attaches it to the future vertebral column and carries the bloodvessels for the supply of the gut, is thinned and drawn out to form the **posterior common mesentery**. The portion of this mesentery attached to the greater curvature of the stomach is named the **dorsal mesogastrium**, and the part which suspends the colon is termed the **mesocolon** (Fig. 194). About the sixth week a diverticulum of the gut appears just behind the opening of the vitelline duct, and indicates the future cecum and vermiform process. The part of the loop on the distal side of the cecal diverticulum increases in diameter and forms the future ascending and transverse portions of the large intestine. Until the fifth month the cecal diverticulum has a uniform calibre, but from this time onward its distal part

remains rudimentary and forms the vermiform process, while its proximal part expands to form the cecum. Changes also take place in the shape and position of the stomach. Its dorsal part or greater curvature, to which the dorsal meso-

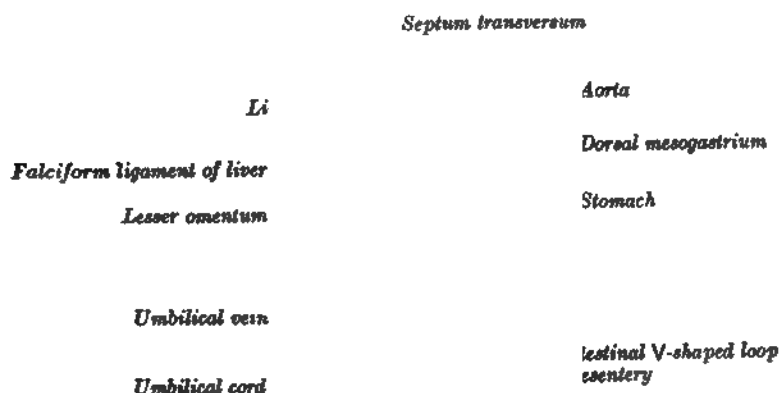

FIG. 193.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)

gastrium is attached, grows much more rapidly than its ventral part or lesser curvature to which the ventral mesogastrium is fixed. Further, the greater curvature is carried downward and to the left, so that the right surface of the stomach is

FIG. 194.—Abdominal part of digestive tube and its attachment to the primitive or common mesentery Human embryo of six weeks. (After Toldt.)

now directed backward and the left surface forward (Fig. 195), a change in position which explains why the left vagus nerve is found on the front, and the right vagus on the back of the stomach. The dorsal mesogastrium being attached to the greater

curvature must necessarily follow its movements, and hence it becomes greatly elongated and drawn lateralward and ventralward from the vertebral column, and, as in the case of the stomach, the right surfaces of both the dorsal and ventral mesogastria are now directed backward, and the left forward. In this way a pouch, the *bursa omentalis*, is formed behind the stomach, and this increases in size as the digestive tube undergoes further development; the entrance to the pouch constitutes the future *foramen epiploicum* or *foramen of Winslow*. The duodenum is developed from that part of the tube which immediately succeeds the stomach; it undergoes little elongation, being more or less fixed in position by the liver and

FIG. 195.—Reconstruction of a human embryo of 17 mm. (After Mall.)

pancreas, which arise as diverticula from it. The duodenum is at first suspended by a mesentery, and projects forward in the form of a loop. The loop and its mesentery are subsequently displaced by the transverse colon, so that the right surface of the duodenal mesentery is directed backward, and, adhering to the parietal peritoneum, is lost. The remainder of the digestive tube becomes greatly elongated, and as a consequence the tube is coiled on itself, and this elongation demands a corresponding increase in the width of the intestinal attachment of the mesentery, which becomes folded.

At this stage the small and large intestines are attached to the vertebral column

by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.¹

The gut is now rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cecum is placed immediately below the liver; about the sixth month the cecum descends into the right iliac fossa, and the large intestine forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (Fig. 197). Sometimes the downward progress of the cecum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

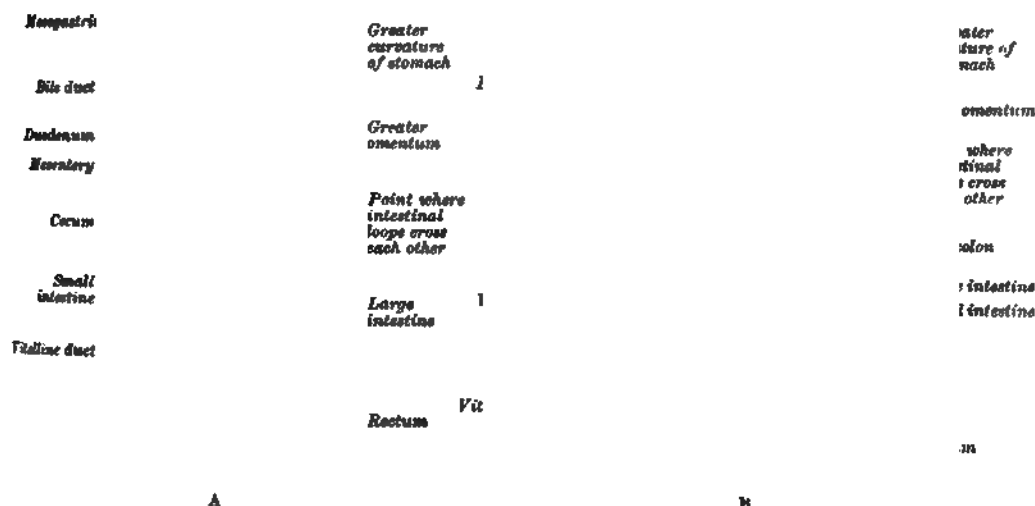

FIG. 196.—Diagrams to illustrate two stages in the development of the digestive tube and its mesentery. The arrow indicates the entrance to the bursa omentalis.

Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the stomach, grows downward to form the greater omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine (Fig. 198). Above, before the pleuro-peritoneal opening is closed, the bursa omentalis sends up a diverticulum on either side of the œsophagus; the left diverticulum soon disappears, but the right is constricted off and persists in most adults as a small sac lying within the thorax on the right side of the lower end of the œsophagus. The anterior layer of the transverse mesocolon is at first distinct from the posterior layer of the greater omentum, but ultimately the two blend, and hence the greater omentum appears as if attached to the transverse colon (Fig. 199). The mesenteries of the ascending and descending parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

¹ Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the median plane, where it is continued into the jejunum, the arteries to the small intestine (*aa. intestinales*) also arise from the right instead of the left side of the superior mesenteric artery.

The lesser omentum is formed, as indicated above, by a thinning of the mesoderm or **ventral mesogastrium**, which attaches the stomach and duodenum to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoderm is divided into two parts, viz., the lesser omentum between the stomach and liver, and the falciform and coronary ligaments between the liver and the abdominal wall and Diaphragma (Fig. 198).

The Rectum and Anal Canal.—The hind-gut is at first prolonged backward into the body-stalk as the tube of the allantois; but, with the growth and flexure of the tail-end of the embryo, the body-stalk, with its contained allantoic tube, is carried forward to the ventral aspect of the body, and consequently a bend is formed at the junction of the hind-gut and allantois. This bend becomes dilated into a pouch, which constitutes the **entodermal cloaca**; into its dorsal part the hind-gut opens, and from its ventral part the allantois passes forward. At a later stage the Wolffian and Müllerian ducts open into its ventral portion. The cloaca is, for a time, shut

FIG. 198.—Schematic figure of the bursa omentalis, etc. Human embryo of eight weeks. (Kollmann.)

off from the anterior by a membrane, the **cloacal membrane**, formed by the apposition of the ectoderm and entoderm, and reaching, at first, as far forward as the future umbilicus. Behind the umbilicus, however, the mesoderm subsequently extends to form the lower part of the abdominal wall and symphysis pubis. By the growth of the surrounding tissues the cloacal membrane comes to lie at the bottom of a depression, which is lined by ectoderm and named the **ectodermal cloaca** (Fig. 200).

The entodermal cloaca is divided into a dorsal and a ventral part by means of a partition, the **urorectal septum** (Fig. 201), which grows downward from the ridge separating the allantoic from the cloacal opening of the intestine and ultimately fuses with the cloacal membrane and divides it into an anal and a urogenital part. The dorsal part of the cloaca forms the rectum, and the anterior part of the urogenital sinus and bladder. For a time a communication named the **cloacal duct** exists between the two parts of the cloaca below the urorectal septum; this duct

occasionally persists as a passage between the rectum and urethra. The anal canal is formed by an invagination of the ectoderm behind the urorectal septum.

This invagination is termed the **proctodæum**, and it meets with the entoderm of the hind-gut and forms with it the **anal membrane**. By the absorption of this membrane the anal canal becomes continuous with the rectum (Fig. 202). A small part of the hind-gut projects backward beyond the anal membrane; it is named the **post-anal gut** (Fig. 200), and usually becomes obliterated and disappears.¹

The Liver.—The liver arises in the form of a diverticulum or hollow outgrowth from the ventral surface of that portion of the gut which afterward becomes the descending part of the duodenum (Figs. 191, 203). This diverticulum is lined by entoderm, and grows upward and forward into the septum transversum, a mass of mesoderm between the vitelline duct and the pericardial cavity, and there gives off two solid buds of cells which represent the right and the left lobes of the liver. The solid buds of cells grow into columns or cylinders, termed the **hepatic cylinders**, which branch and anastomose to form a close meshwork. This network invades the vitelline and umbilical veins, and breaks up these vessels into a series of capillary-like vessels termed **sinusoids** (Minot), which ramify in the meshes of the cellular network and ultimately form the venous capillaries of the liver. By the continued

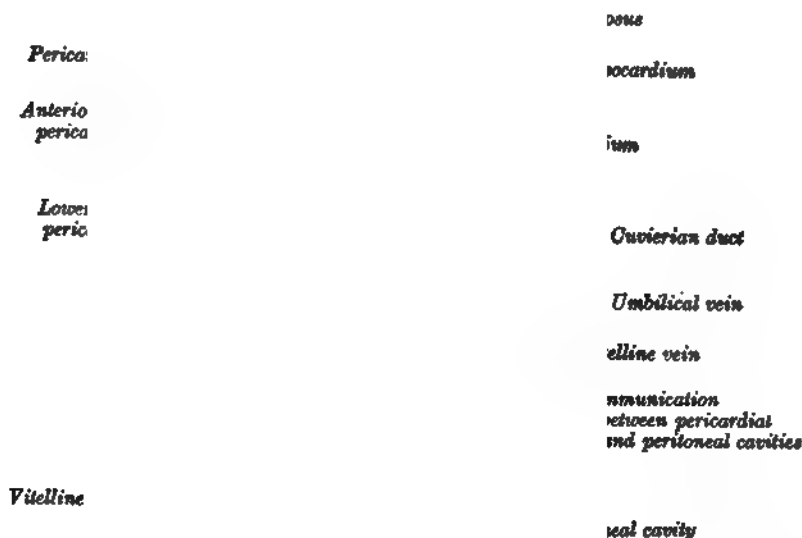

FIG. 203.—Liver with the septum transversum. Human embryo 3 mm. long. (After model and figure by His.)

growth and ramification of the hepatic cylinders the mass of the liver is gradually formed. The original diverticulum from the duodenum forms the common bile-duct, and from this the cystic duct and gall-bladder arise as a solid outgrowth which later acquires a lumen. The opening of the common duct is at first in the ventral wall of the duodenum; later, owing to the rotation of the gut, the opening is carried to the left and then dorsalward to the position it occupies in the adult.

As the liver undergoes enlargement, both it and the ventral mesogastrium of the fore-gut are gradually differentiated from the septum transversum; and from the under surface of the latter the liver projects downward into the abdominal cavity. By the growth of the liver the ventral mesogastrium is divided into two parts, of which the anterior forms the falciform and coronary ligaments, and the posterior the lesser omentum. About the third month the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right. From this period

¹ Consult, in this connection, the following article: "A Contribution to the Morphology of the Human Urinogenital Tract," by D. Berry Hart, M.D., F.R.C.P.E., *Journal of Anatomy and Physiology*, April, 1901, vol. xxxiv.

the relative development of the liver is less active, more especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right; but up to the end of fetal life the liver remains relatively larger than in the adult.

The Pancreas (Figs. 204, 205).—The pancreas is developed in two parts, a dorsal and a ventral. The former arises as a diverticulum from the dorsal aspect of the duodenum a short distance above the hepatic diverticulum, and, growing upward and backward into the dorsal mesogastrium, forms a part of the head and uncinæ process and the whole of the body and tail of the pancreas. The ventral

FIG. 205.—Pancreas of a human embryo at end of sixth week. (Kollmann.)

part appears in the form of a diverticulum from the primitive bile-duct and forms the remainder of the head and uncinæ process of the pancreas. The duct of the dorsal part (accessory pancreatic duct) therefore opens independently into the duodenum, while that of the ventral part (pancreatic duct) opens with the common bile-duct. About the sixth week the two parts of the pancreas meet and fuse and a communication is established between their ducts. After this has occurred the terminal part of the accessory duct, *i. e.*, the part between the duodenum and the point of meeting of the two ducts, undergoes little or no enlargement, while

the pancreatic duct increases, in size and forms, the main duct of the gland. The opening of the accessory duct into the duodenum is sometimes obliterated, and even when it remains patent it is probable that the whole of the pancreatic secretion is conveyed through the pancreatic duct.

At first the pancreas is directed upward and backward between the two layers of the dorsal mesogastrium, which give to it a complete peritoneal investment, and its surfaces look to the right and left. With the change in the position of the stomach the dorsal mesogastrium is drawn downward and to the left, and the right side of the pancreas is directed backward and the left forward (Fig. 206). The

right surface becomes applied to the posterior abdominal wall, and the peritoneum which covered it undergoes absorption (Fig. 207); and thus, in the adult, the gland appears to lie behind the peritoneal cavity.

FIG. 207.—Section through same region as in Fig. 206, at end of third month. (Toldt.)

The Spleen (Fig. 194).—Although the spleen belongs to the group of ductless glands, its development may be conveniently referred to here. It appears about the fifth week as a localized thickening of the mesoderm in the dorsal mesogastrium above the tail of the pancreas. With the change in position of the stomach the spleen is carried to the left, and comes to lie behind the stomach and in contact with the left kidney. The part of the dorsal mesogastrium which intervened between the spleen and the greater curvature of the stomach forms the gastro-splenic ligament.

FIG. 208.—The head and neck of a human embryo thirty-two days old, seen from the ventral surface. The floor of the mouth and pharynx have been removed. (His.)

The Respiratory Organs.—The rudiment of the respiratory organs appear as a median longitudinal groove in the ventral wall of the pharynx. The groove deepens and its lips fuse to form a septum which grows from below upward and converts the groove into a tube, the **laryngo-tracheal tube** (Fig. 208), the cephalic end of which opens into the pharynx by a slit-like aperture formed by the persistent anterior part of the groove. The tube is lined by entoderm from which the epithelial lining of the respiratory tract is developed. The cephalic part of the tube

becomes the larynx, and its next succeeding part the trachea, while from its caudal end two lateral outgrowths, the right and left lung buds, arise, and from them the bronchi and lungs are developed. The first rudiment of the larynx consists of two **arytenoid swellings**, which appear, one on either side of the cephalic end of the laryngo-tracheal groove, and are continuous in front of the groove with a transverse ridge (*furcula of His*) which lies between the ventral ends of the third branchial arches and from which the epiglottis is subsequently developed (Figs. 187, 188). After the separation of the trachea from the oesophagus, the arytenoid swellings come into contact with one another and with the back of the epiglottis, and the entrance to the larynx assumes the form of a T-shaped cleft, the margins of the cleft adhere to one another and the laryngeal entrance is for a time occluded. The mesodermal wall of the tube becomes condensed to form the cartilages of the larynx and trachea. The arytenoid swellings are differentiated into the arytenoid and corniculate cartilages, and the folds joining them to the epiglottis form the aryepiglottic folds in which the cuneiform cartilages are developed as derivatives of the epiglottis. The thyroid cartilage appears as two lateral plates, each chondrified from two centres and united in the mid-ventral line by membrane in which an additional centre of chondrification develops. The cricoid cartilage arises from two cartilaginous centres, which soon unite ventrally and gradually extend and ultimately fuse on the dorsal aspect of the tube.

J. Ernest Fraser¹ has made an important investigation on the development of the larynx, and the following are his main conclusions:

The opening of the pulmonary diverticulum lies between the two fifth arch masses and behind a "central mass" in the middle line—the proximal end of the diverticulum is compressed between the fifth arch masses. The fifth arch is joined by the fourth to form a "lateral mass" on each side of the opening, and these "lateral masses" grow forward and overlap the central mass and so form a secondary transverse cavity, which is really a part of the cavity of the pharynx. The two parts of the cavity of the larynx are separated in the adult by a line drawn back along the vocal fold and then upward along the border of the arytenoid eminence to the interarytenoid notch. The arytenoid and cricoid are developed in the fifth arch mass. The thyroid is primarily a fourth arch derivative, and if it has a fifth arch element this is a later addition. The epiglottis is derived from the "central mass," and has a third arch element in its oral and upper aspect; the arch value of the "central mass" is doubtful.

FIG. 209.—Lung buds from a human embryo of about four weeks, showing commencing lobulations. (Hm.)

FIG. 210.—Lungs of a human embryo more advanced in development. (His.)

The right and left lung buds grow out behind the ducts of Cuvier, and are at first symmetrical, but their ends soon become lobulated, three lobules appearing on the right, and two on the left; these subdivisions are the early indications of the corresponding lobes of the lungs (Figs. 209, 210). The buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the infundibula of the lung. After the sixth month the air-sacs begin to make their appearance on the infundibula in the form of minute pouches. The pulmonary arteries are derived from the sixth aortic arches. During the course of their development the lungs migrate in a caudal direction, so that by the time of birth

¹ *Journal of Anatomy and Physiology*, vol. xlii.

the bifurcation of the trachea is opposite the fourth thoracic vertebra. As the lungs grow they project into that part of the coelom which will ultimately form the pleural cavities, and the superficial layer of the mesoderm enveloping the lung rudiment expands on the growing lung and is converted into the pulmonary pleura.

DEVELOPMENT OF THE BODY CAVITIES.

In the human embryo described by Peters the mesoderm outside the embryonic disk is split into two layers enclosing an extra-embryonic coelom; there is no trace of an intra-embryonic coelom. At a later stage four cavities are formed within the embryo, viz., one on either side within the mesoderm of the pericardial area, and one in either lateral mass of the general mesoderm. All these are at first independent of each other and of the extra-embryonic coelom, but later they become continuous. The two cavities in the general mesoderm unite on the ventral aspect of the gut and form the pleuro-peritoneal cavity, which becomes continuous with the remains of the extra-embryonic coelom around the umbilicus; the two cavities in the pericardial area rapidly join to form a single pericardial cavity, and from this two lateral

FIG. 211.—Figure obtained by combining several successive sections of a human embryo of about the fourth week (From Kollmann.) The upper arrow is in the pleuroperitoneal opening, the lower in the pleuropericardial.

diverticula extend caudalward to open into the pleuro-peritoneal cavity (Fig. 211). Between the two latter diverticula is a mass of mesoderm containing the ducts of Cuvier, and this is continuous ventrally with the mesoderm in which the umbilical veins are passing to the sinus venosus. A septum of mesoderm thus extends across the body of the embryo. It is attached in front to the body-wall between the pericardium and umbilicus; behind to the body-wall at the level of the second cervical segment; laterally it is deficient where the pericardial and pleuro-peritoneal cavities communicate, while it is perforated in the middle line by the fore-gut. This partition is termed the **septum transversum**, and is at first a bulky plate of tissue. As development proceeds the dorsal end of the septum is carried gradually caudalward, and when it reaches the fifth cervical segment muscular tissue with the phrenic nerve grow into it. It continues to recede, however, until it reaches the position of the adult Diaphragma on the bodies of the upper lumbar vertebrae. As already described (page 174), the liver buds grow into the septum transversum and undergo development there.

The lung buds meantime have grown out from the fore-gut, and project laterally into the forepart of the pleuro-peritoneal cavity; the developing stomach and liver

are imbedded in the septum transversum; caudal to this the intestines project into the back part of the pleuro-peritoneal cavity (Fig. 212). Owing to the descent of the dorsal end of the septum transversum the lung buds come to lie above the

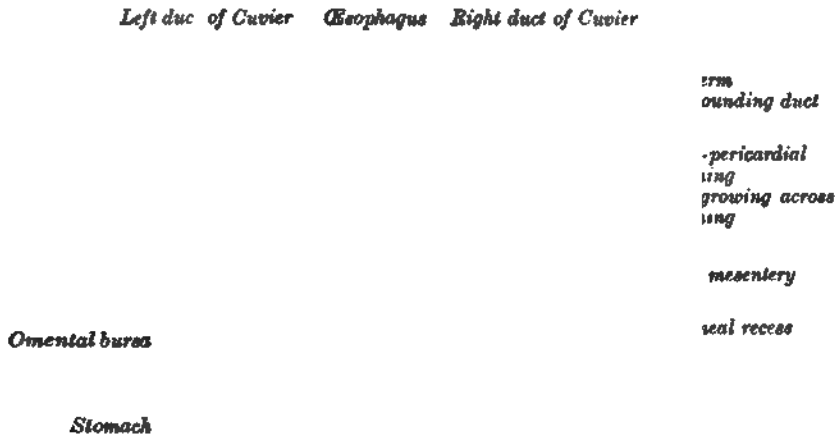

FIG. 212.—Upper part of coelom of human embryo of 6.8 mm., seen from behind. (From model by Piper.)

septum and thus pleural and peritoneal portions of the pleuro-peritoneal cavity (still, however, in free communication with one another) may be recognized; the pericardial cavity opens into the pleural part.

The ultimate separation of the permanent cavities from one another is effected by the growth of a ridge of tissue on either side from the mesoderm surrounding

FIG. 213.—Diagram of transverse section through rabbit embryo. (After Keith.)

the duct of Cuvier (Figs. 211, 212). The front part of this ridge grows across and obliterates the pleuro-pericardial opening; the hinder part grows across the pleuro-peritoneal opening.

With the continued growth of the lungs the pleural cavities are pushed forward in the body-wall toward the ventral median line, thus separating the pericardium from the lateral thoracic walls (Fig. 213). The further development of the peritoneal cavity has been described with the development of the digestive tube (page 168 *et seq.*).

FIG. 214.—The thoracic aspect of the Diaphragm of a newly born child in which the communication between the peritoneum and pleura has not been closed on the left side; the position of the opening is marked on the right side by the spinocostal hiatus. (After Keith.)

DEVELOPMENT OF THE URINARY AND GENERATIVE ORGANS.

The urinary and generative organs are developed from the intermediate cell-mass which is situated between the primitive segments and the lateral plates of mesoderm. The permanent organs of the adult are preceded by a set of structures which are purely embryonic, and which with the exception of the ducts disappear almost entirely before the end of fetal life. These embryonic structures are on either side; the **pronephros**, the **mesonephros**, the **metanephros**, and the **Wolffian** and **Müllerian ducts**. The pronephros disappears very early; the structural elements of the mesonephros mostly degenerate, but in their place is developed the genital gland in association with which the Wolffian duct remains as the duct of the male genital gland, the Müllerian as that of the female; some of the tubules of the metanephros form part of the permanent kidney.

The Pronephros and Wolffian Duct.—In the outer part of the intermediate cell-mass, immediately under the ectoderm, in the region from the fifth cervical to the third thoracic segments, a series of short evaginations from each segment grow dorsalward and extend caudalward, fusing successively from before backward to form the **pronephric duct**. This continues to grow caudalward until it opens into the ventral part of the cloaca; beyond the pronephros it is termed the **Wolffian duct**.

The original evaginations form a series of transverse tubules each of which communicates by means of a funnel-shaped ciliated opening with the coelomic cavity, and in the course of each duct a glomerulus also is developed. Secondary glomeruli are formed ventral to each of the others, and the complete group constitutes the **pronephros**. The pronephros undergoes rapid atrophy and disappears.

The Mesonephros, Müllerian Duct, and Genital Gland.—On the medial side of the Wolffian duct, from the sixth cervical to the third lumbar segments, a series of tubules, the **Wolffian tubules** (Fig. 215), is developed; at a later stage in development they increase in number by outgrowths from the original tubules. These tubules first appear as solid masses of cells, which later become hollowed in the

centre; one end grows toward and finally opens into the Wolffian duct, the other dilates and is invaginated by a tuft of capillary bloodvessels to form a glomerulus. The tubules collectively constitute the *mesonephros* or *Wolffian body* (Figs. 195, 216). By the fifth or sixth week this body forms an elongated spindle-shaped structure, termed the *urogenital fold* (Fig. 215), which projects into the coelomic cavity at the side of the dorsal mesentery, reaching from the septum transversum

FIG. 215.—Section of the urogenital fold of a chick embryo of the fourth day. (Waldeyer.)

in front to the fifth lumbar segment behind; in this fold the reproductive glands are developed. The Wolffian bodies persist and form the permanent kidneys in fishes and amphibians, but in reptiles, birds, and mammals, they atrophy and for the most part disappear coincidently with the development of the permanent kidneys. The atrophy begins during the sixth or seventh week and rapidly proceeds, so that by the beginning of the fifth month only the ducts and a few of the tubules remain.

In the male the Wolffian duct persists, and forms the tube of the epididymis, the ductus deferens and the ejaculatory duct, while the seminal vesicle arises during the third month as a lateral diverticulum from its hinder end. A large part of the head end of the mesonephros atrophies and disappears; of the remainder the anterior tubules form the efferent ducts of the testis; while the posterior tubules are represented by the ductuli aberrantes, and by the paradidymis, which is sometimes found in front of the spermatic cord above the head of the epididymis (Fig. 219, C).

In the female the Wolffian bodies and ducts atrophy. The remains of the Wolffian tubules are represented by the *epoöphoron* or *organ of Rosenmüller*, and the *paroöphoron*, two small collections of rudimentary blind tubules which are situated in the mesosalpinx (Fig. 217). The lower part of the Wolffian duct

disappears, while the upper part persists as the longitudinal duct of the epoöphoron or duct of Gärtner¹ (Fig. 219, *B*).

The Müllerian Ducts.—Shortly after the formation of the Wolffian ducts a second pair of ducts is developed; these are named the **Müllerian ducts**. Each arises on the lateral aspect of the corresponding Wolffian duct as a tubular invagination of the cells lining the coelom (Fig. 215). The orifice of the invagination

FIG. 217.—Broad ligament of adult, showing epoöphoron. (From Farre, after Kobelt.) *a, a.* Epoöphoron formed from the upper part of the Wolffian body. *b.* Remains of the uppermost tubes sometimes forming appendices. *c.* Middle set of tubes. *d.* Some lower atrophied tubes. *e.* Atrophied remains of the Wolffian duct. *f.* The terminal bulb or hydatid. *h.* The uterine tube, originally the duct of Müller. *i.* Appendix attached to the extremity. *l.* The ovary.

remains patent, and undergoes enlargement and modification to form the abdominal ostium of the uterine tube. The ducts pass backward lateral to the Wolffian ducts, but toward the posterior end of the embryo they cross to the medial side of these ducts, and thus come to lie side by side between and behind the latter—the four ducts forming what is termed the **genital cord** (Fig. 218). The Müllerian ducts end in an epithelial elevation, the **Müllerian eminence**, on the ventral part of the cloaca between the orifices of the Wolffian ducts; at a later date they open into the cloaca in this situation.

Müllerian ducts

In the male the Müllerian ducts atrophy, but traces of their anterior ends are represented by the **appendices testis** (*hydatids of Morgagni*), while their terminal fused portions form the utriculus in the floor of the prostatic portion of the urethra (Fig. 219, *C*).

In the female the Müllerian ducts persist and undergo further development. The portions which lie in the genital core fuse to form the uterus and vagina; the parts in front of this cord remain separate, and each forms the corresponding uterine tube—the abdominal ostium of which is developed from the anterior extremity of the original tubular invagination from the coelom (Fig. 219, *B*). The

emin.

FIG. 218.—Urogenital sinus of female human embryo of eight and a half to nine weeks old. (From model by Keibel)

fusion of the Müllerian ducts begins in the third month, and the septum formed by their fused medial walls disappears from below upward, and thus the cavities

¹ Berry Hart (*op. cit.*) has described the Wolffian ducts as ending at the site of the future hymen in bulbous enlargements, which he has named the *Wolffian bulbs*; and states that the hymen is formed by these bulbs, "aided by a special involution from below of the cells lining the urogenital sinus." He further believes that "the lower third of the vagina is due to the coalescence of the upper portion of the urogenital sinus and the lower ends of the Wolffian ducts," and that "the epithelial lining of the vagina is derived from the Wolffian bulbs." He also regards the colliculus seminalis of the male urethra as being formed from the lower part of the Wolffian ducts.

of the vagina and uterus are produced. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. For a time the vagina is represented by a solid rod of epithelial cells. A ring-like outgrowth of this epithelium occurs at the lower end of the uterus and marks the future vaginal fornices; about the fifth or sixth month the lumen of the vagina is produced by the breaking down of the central cells of the epithelium. The hymen represents the remains of the Müllerian eminence.

Genital Glands.—The first appearance of the genital gland is essentially the same in the two sexes, and consists in a thickening of the epithelial layer which lines the peritoneal cavity on the medial side of the urogenital fold (Fig. 215). The thick plate of epithelium extends deeply, pushing before it the mesoderm and forming a distinct projection. This is termed the **genital ridge** (Fig. 215), and from it the testis in the male and the ovary in the female are developed. At first the mesonephros and genital ridge are suspended by a common mesentery, but as the embryo grows the genital ridge gradually becomes pinched off from the mesone-

phros, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the **mesorchium** or **mesovarium** (Fig. 220). About the seventh week the distinction of sex in the genital ridge begins to be perceptible.

The Ovary.—The ovary, thus formed from the genital ridge, is at first a mass of cells derived from the coelomic epithelium; later the mass is differentiated into a central part or medulla (Fig. 221) covered by a surface layer, the **germinal epithelium**. Between the cells of the germinal epithelium a number of larger cells, the **primitive ova**, are found, and these are carried into the subjacent stroma by bud-like ingrowths (**genital cords**) of the germinal epithelium (Fig. 222). The surface epithelium ultimately forms the permanent epithelial covering of this organ; it soon loses its connection

FIG. 220.—Transverse section of human embryo eight and a half to nine weeks old. (From model by Kolbel.)

with the central mass, and a tunica albuginea develops between them. The ova are chiefly derived from the cells of the central mass; these are separated from one another by the growth of connective tissue in an irregular manner; each ovum assumes a covering of connective tissue (follicle) cells, and in this way the rudiments of the ovarian follicles are formed (Fig. 222). According to Beard the primitive ova are early set apart during the segmentation of the ovum and migrate into the germinal ridge.

Waldeyer taught that the primitive germ cells are derived from the "germinal epithelium," covering the genital ridge. Beard,¹ on the other hand, maintains that in the skate they are not derived from this epithelium, but are probably formed during the later stages of cell cleavage, before there is any trace of an embryo; and a similar view was advanced by Nussbaum as to their origin in amphibia. Beard says: "At the close of segmentation many of the future germ cells lie in the segmentation cavity just beneath the site of the future embryo, and there is no doubt they subsequently wander into it." The germ cells, "after they enter the resting phase, are

¹ Journal of Anatomy and Physiology, vol. xxxviii.

sharply marked off from the cells of the embryo by entire absence of mitoses among them." They can be further recognized by their irregular form and amoeboid processes, and by the fact

FIG. 221.—Longitudinal section of ovary of cat embryo of 9.4 cm. long. Schematic. (After Coert.)

that their cytoplasm has no affinity for ordinary stains, but assumes a brownish tinge when treated by osmic acid. The path along which they travel into the embryo is a very definite one, viz., "from the yolk sac upward between the splanchnopleure and gut in the hinder portion of the

FIG. 222.—Section of the ovary of a newly born child. (Waldeyer.)

embryo." This pathway, named by Beard the **germinal path**, "leads them directly to the position which they ought finally to take up in the 'germinal ridge' or nidus." A considerable number

apparently never reach their proper destination, since "vagrant germ cells are found in all sorts of places, but more particularly on the mesentery." Some of these may possibly find their way into the germinal ridge; some probably undergo atrophy, while others may persist and become the seat of dermoid tumors.

The Testis.—The testis is developed in much the same way as the ovary. Like the ovary, in its earliest stages it consists of a central mass of epithelium covered by a surface epithelium. In the central mass a series of cords appear (Fig. 223), and the periphery of the mass is converted into the tunica albuginea, thus excluding the surface epithelium from any part in the formation of the tissue of the testis. The cords of the central mass run together toward the future hilus and form a network which ultimately becomes the rete testis. From the cords the seminiferous tubules are developed, and between them connective tissue septa extend. The seminiferous tubules become connected with outgrowths from the Wolffian body, which, as before mentioned, form the efferent ducts of the testis.

Descent of the Testes.—The testes, at an early period of fetal life, are placed at the back part of the abdominal cavity, behind the peritoneum, and each is

Epithelium

albuginea*

*Interstitial
cell*

*Supporting
cell*

*Genital
cell*

attached by a peritoneal fold, the **mesorchium**, to the mesonephros. From the front of the mesonephros a fold of peritoneum termed the **inguinal fold** grows forward to meet and fuse with a peritoneal fold, the **inguinal crest**, which grows backward from the antero-lateral abdominal wall. The testis thus acquires an indirect connection with the anterior abdominal wall; and at the same time a portion of the peritoneal cavity lateral to these fused folds is marked off as the future **saccus vaginalis**. In the inguinal crest a peculiar structure, the **gubernaculum testis**, makes its appearance. This is at first a slender band, extending from that part of the skin of the groin which afterward forms the scrotum through the inguinal

FIG. 223.—Section of a genital cord of the testis of a human embryo 3.5 cm. long. (Felix and Bühler.)

canal to the body and epididymis of the testis. As development advances, the peritoneum enclosing the gubernaculum forms two folds, one above the testis and the other below it. The one above the testis is the **plica vascularis**, and contains ultimately the internal spermatic vessels; the one below, the **plica gubernatrix**, contains the lower part of the gubernaculum, which has now grown into a thick cord; it ends below at the abdominal inguinal ring in a tube of peritoneum, the **saccus vaginalis**, which protrudes itself down the inguinal canal. By the fifth month the lower part of the gubernaculum has become a thick cord, while the upper part has disappeared. The lower part now consists of a central core of unstriped muscle fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. As the scrotum develops, the main portion of the lower end of the gubernaculum is carried, with the skin to which it is attached, to the bottom of this pouch; other bands are carried to the medial side of the thigh and to the perineum. The tube of peritoneum constituting the **saccus vaginalis** projects itself downward into the inguinal canal, and emerges at the cutaneous inguinal ring, pushing before it a part of the **Obliquus internus** and the aponeurosis of the **Obliquus externus**, which form respectively

the Cremaster muscle and the intercrural fascia. It forms a gradually elongating pouch, which eventually reaches the bottom of the scrotum, and behind this pouch the testis is drawn by the growth of the body of the fetus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testis, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal and eventually into the scrotum. It seems certain also that the gubernacular cord becomes shortened as development proceeds, and this assists in causing the testis to reach the bottom of the scrotum. By the end of the eighth month the testis has reached the scrotum, preceded by the saccus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the saccus vaginalis usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis is now entirely cut off from the general peritoneal cavity and constitutes the *tunica vaginalis*.

Descent of the Ovaries.—In the female there is also a gubernaculum, which effects a considerable change in the position of the ovary, though not so extensive a change as in that of the testis. The gubernaculum in the female lies in contact with the fundus of the uterus and contracts adhesions to this organ, and thus the ovary is prevented from descending below this level. The part of the gubernaculum between the ovary and the uterus becomes ultimately the proper ligament of the ovary, while the part between the uterus and the labium majus forms the round ligament of the uterus. A pouch of peritoneum analogous to the saccus vaginalis in the male accompanies it along the inguinal canal: it is called the *canal of Nuck*. In rare cases the gubernaculum may fail to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labium majus, and under these circumstances its position resembles that of the testis.

Wolffian duct

notch

FIG. 224.—Tail end of human embryo twenty-five to twenty-nine days old. (From model by Keibel.)

FIG. 225.—Tail end of human embryo thirty-two to thirty-three days old. (From model by Keibel.)

The Metanephros and the Permanent Kidney.—The rudiments of the permanent kidneys make their appearance about the end of the first or the beginning of the second month. Each kidney has a two-fold origin, part arising from the metanephros, and part as a diverticulum from the hind-end of the Wolffian duct, close to where the latter opens into the cloaca (Figs. 224, 225). The metanephros arises in the intermediate cell mass, caudal to the mesonephros, which it resembles in structure. The diverticulum from the Wolffian duct grows dorsalward and forward along the posterior abdominal wall, where its blind extremity expands and subsequently divides into several buds, which form the rudiments of the pelvis and calices of the kidney; by continued growth and subdivision it gives rise to the collecting tubules of the kidney. The proximal portion of the diverticulum becomes the ureter. The secretory tubules are developed from the

metanephros, which is moulded over the growing end of the diverticulum from the Wolffian duct. The tubules of the metanephros, unlike those of the pronephros and mesonephros, do not open into the Wolffian duct. One end expands to form a glomerulus, while the rest of the tubule rapidly elongates to form the convoluted and straight tubules, the loops of Henle, and the connecting tubules; these last

join and establish communications with the collecting tubules derived from the ultimate ramifications of the diverticulum from the Wolffian duct. The mesoderm around the tubules becomes condensed to form the connective tissue of the kidney. The ureter opens at first into the hind-end of the Wolffian duct; after the sixth week it separates from the Wolffian duct, and opens independently into the part of the cloaca which ultimately becomes the bladder (Figs. 226, 227).

The secretory tubules of the kidney become arranged into pyramidal masses or lobules, and the lobulated condition of the kidneys exists for some time after birth, while traces of

it may be found even in the adult. The kidney of the ox and many other animals remains lobulated throughout life.

The Urinary Bladder.—The bladder is formed partly from the entodermal cloaca and partly from the ends of the Wolffian ducts; the allantois takes no share in its formation. After the separation of the rectum from the dorsal part of the

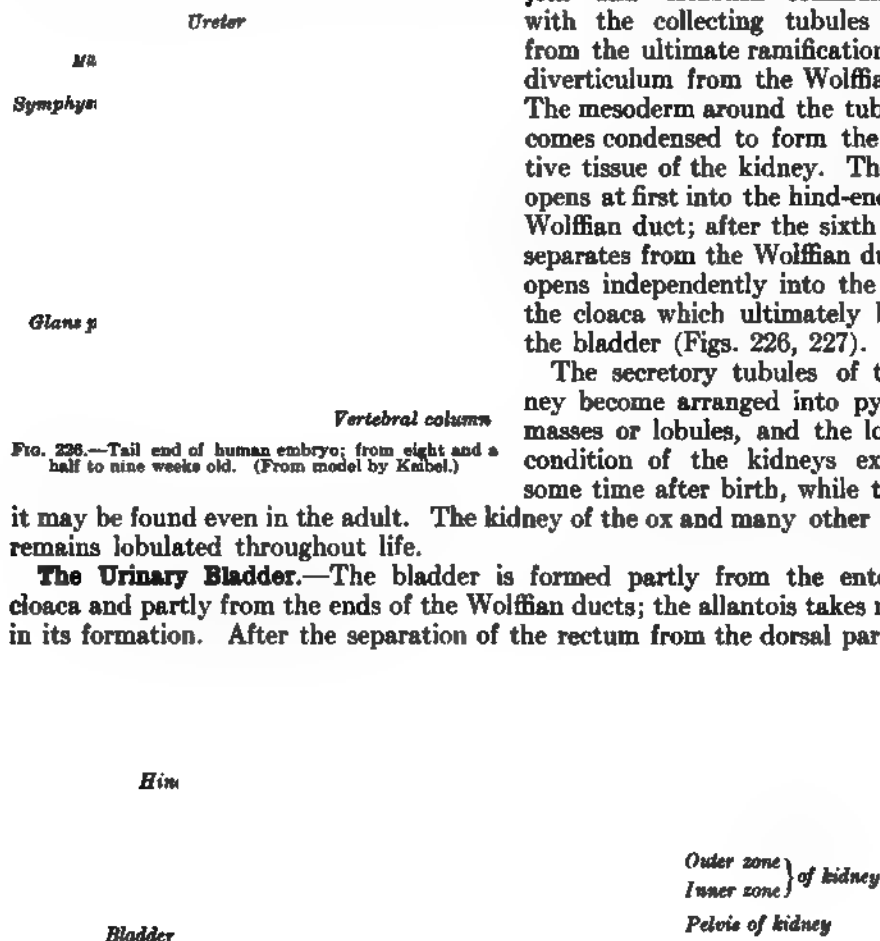

FIG. 227.—Primitive kidney and bladder, from a reconstruction. (After Schreiner.)

cloaca (p. 172), the ventral part becomes subdivided into three portions: (1) an anterior **vesico-urethral portion**, continuous with the allantois—into this portion the Wolffian ducts open; (2) an intermediate narrow channel, the **pelvic portion**; and (3) a posterior **phallic portion**, closed externally by the urogenital membrane (Fig. 227). The second and third parts together constitute the **urogenital sinus**. The

vesico-urethral portion absorbs the ends of the Wolffian ducts and the associated ends of the renal diverticula, and these give rise to the trigone of the bladder and part of the prostatic urethra. The remainder of the vesico-urethral portion forms the body of the bladder and part of the prostatic urethra; its apex is prolonged to the umbilicus as a narrow canal, which later is obliterated and becomes the medial umbilical ligament (urachus).

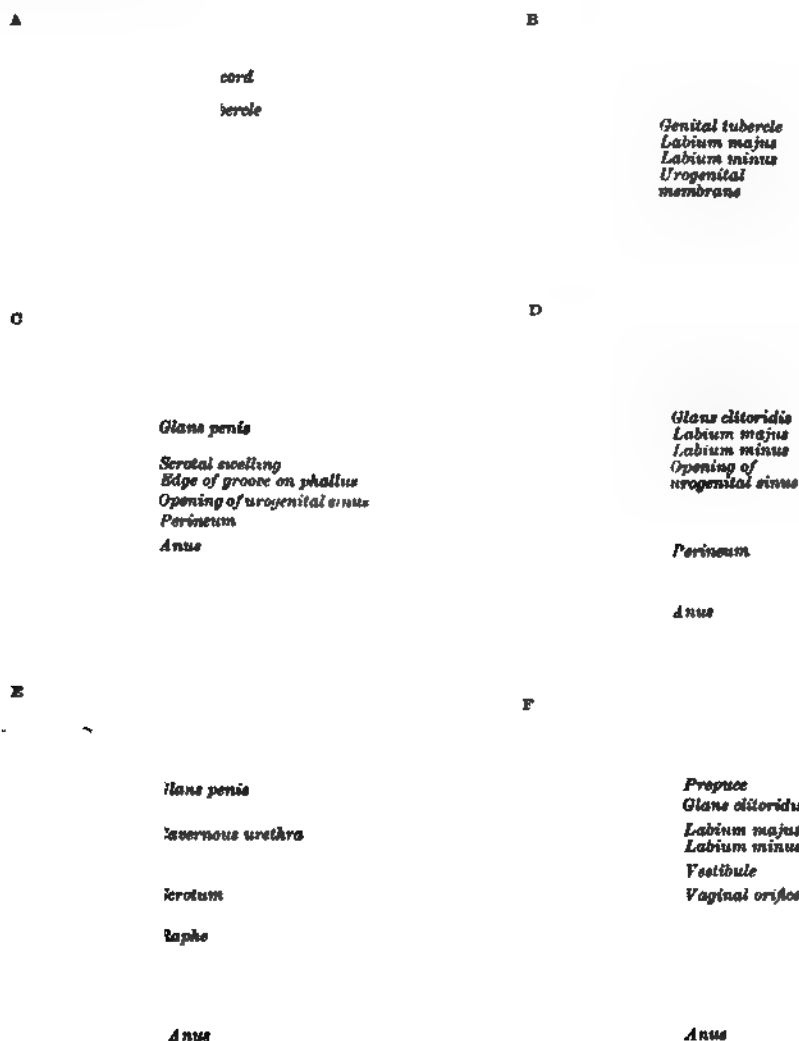

FIG. 228.—Stages in the development of the external sexual organs in the male and female. (Drawn from the Ecker-Ziegler models.)

The Prostate.—The prostate originally consists of two separate portions, each of which arises as a series of diverticular buds from the epithelial lining of the urogenital sinus and vesico-urethral part of the cloaca, between the third and fourth months. These buds become tubular, and form the glandular substance of the two lobes, which ultimately meet and fuse behind the urethra and also extend on to its ventral aspect. The isthmus or middle lobe is formed as an extension of the lateral

lobes between the common ejaculatory ducts and the bladder. **Skene's ducts** in the female urethra are regarded as the homologues of the prostatic glands.

The **bulbo-urethral glands of Cowper** in the male, and **greater vestibular glands of Bartholin** in the female, also arise as diverticula from the epithelial lining of the urogenital sinus.

The External Organs of Generation (Fig. 228).—As already stated (page 172), the cloacal membrane, composed of ectoderm and entoderm, originally reaches from the umbilicus to the tail. The mesoderm extends to the midventral line for some distance behind the umbilicus, and forms the lower part of the abdominal wall; it ends below in a prominent swelling, the **cloacal tubercle**. Behind this tubercle the urogenital part of the cloacal membrane separates the ingrowing sheets of mesoderm.

The first rudiment of the penis (or clitoris) is a structure termed the **phallus**; it is derived from the phallic portion of the cloaca which has extended on to the end and sides of the under surface of the cloacal tubercle. The terminal part of the phallus representing the future glans becomes solid; the remainder, which is hollow, is converted into a longitudinal groove by the absorption of the urogenital membrane.

In the female a deep groove forms around the phallus and separates it from the rest of the cloacal tubercle, which is now termed the **genital tubercle**. The sides of the genital tubercle grow backward as the **genital swellings**, which ultimately form the labia majora; the tubercle itself becomes the mons pubis. The labia minora arise by the continued growth of the lips of the groove on the under surface of the phallus; the remainder of the phallus forms the clitoris.

In the male the early changes are similar, but the pelvic portion of the cloaca undergoes much greater development, pushing before it the phallic portion. The genital swellings extend around between the pelvic portion and the anus, and form a scrotal area; during the changes associated with the descent of the testes this area is drawn out to form the scrotal sacs. The penis is developed from the phallus. As in the female, the urogenital membrane undergoes absorption, forming a channel on the under surface of the phallus; this channel extends only as far forward as the corona glandis.

The **corpora cavernosa** of the penis (or clitoris) and of the urethra arise from the mesodermal tissue in the phallus; they are at first dense structures, but later vascular spaces appear in them, and they gradually become cavernous.

The **prepuce** in both sexes is formed by the growth of a solid plate of ectoderm into the superficial part of the phallus; on coronal section this plate presents the shape of a horseshoe. By the breaking down of its more centrally situated cells the plate is split into two lamellæ, and a cutaneous fold, the prepuce, is liberated and forms a hood over the glans. "Adherent prepuce is not an adhesion really, but a hindered central desquamation" (Berry Hart, *op. cit.*).

The Urethra.—As already described, in both sexes the phallic portion of the cloaca extends on to the under surface of the cloacal tubercle as far forward as the apex. At the apex the walls of the phallic portion come together and fuse, the lumen is obliterated, and a solid plate, the **urethral plate**, is formed. The remainder of the phallic portion is for a time tubular, and then, by the absorption of the urogenital membrane, it establishes a communication with the exterior; this opening is the **primitive urogenital ostium**, and it extends forward to the corona glandis.

In the female this condition is largely retained; the portion of the groove on the clitoris broadens out while the body of the clitoris enlarges, and thus the adult urethral opening is situated behind the base of the clitoris.

In the male, by the greater growth of the pelvic portion of the cloaca a longer urethra is formed, and the primitive ostium is carried forward with the phallus, but it still ends at the corona glandis. Later it closes from behind forward. Mean-

while the urethral plate of the glans breaks down centrally to form a median groove continuous with the primitive ostium. This groove also closes from behind forward, so that the external urethral opening is shifted forward to the end of the glans.

THE FORM OF THE EMBRYO AT DIFFERENT STAGES OF ITS GROWTH.

First Week.—During this period the ovum is in the uterine tube. Having been fertilized in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus. Peters¹ described a specimen, the age of which he reckoned as from three to four days. It was imbedded in the decidua on the posterior wall of the uterus and enveloped by a decidua capsularis, the central part of which, however, consisted merely of a layer of fibrin. The ovum was in the form of a sac, the outer wall of which consisted of a layer of trophoblast; inside this was a thin layer of mesoderm composed of round, oval, and spindle-shaped cells. Numerous villous processes—some consisting of trophoblast only, others possessing a core of mesoderm—projected from the surface of the ovum into the surrounding decidua. Inside this sac the rudiment of the embryo was found in the form of a patch of ectoderm, covered by a small but completely closed amnion. It possessed a minute yolk-sac and was surrounded by mesoderm, which was connected by a band to that lining the trophoblast (Fig. 88).²

Amnion

FIG. 229.—Human embryo about fifteen days old. (His.)

Second Week.—By the end of this week the ovum has increased considerably in size, and the majority of its villi are vascularized. The embryo has assumed a definite form, and its cephalic and caudal extremities are easily distinguished. The neural folds are partly united. The embryo is more completely separated from the yolk-sac, and the paraxial mesoderm is being divided into the primitive segments (Fig. 229).

Third Week.—By the end of the third week the embryo is strongly curved, and the primitive segments number about thirty. The primary divisions of the brain are visible, and the optic and auditory vesicles are formed. Four branchial grooves are present: the stomodeum is well-marked, and the buccopharyngeal membrane has disappeared. The rudiments of the limbs are seen as short buds, and the Wolfian bodies are visible (Fig. 230).

Fourth Week.—The embryo is markedly curved on itself, and when viewed in profile is almost circular in outline. The cerebral hemispheres appear as hollow buds, and the elevations which form the rudiments of the auricula are visible. The limbs now appear as oval flattened projections (Fig. 231).

Fifth Week.—The embryo is less curved and the head is relatively of large size. Differentiation of the limbs into their segments occurs. The nose forms a short, flattened projection. The cloacal tubercle is evident (Fig. 232).

¹ Die Einbettung des menschlichen Eies, 1899.

² Bryce and Teacher (*Early Development and Imbedding of the Human Ovum*, 1908) have described an ovum which they regard as thirteen to fourteen days old. In it the two vesicles, the amnion and yolk-sac, were present, but there was no trace of a layer of embryonic ectoderm. They are of opinion that the age of Peters' ovum has been understated, and estimate it as between thirteen and one-half and fourteen and one-half days.

Sixth Week.—The curvature of the embryo is further diminished. The branchial grooves—except the first—have disappeared, and the rudiments of the fingers and toes can be recognized (Fig. 233).

Mid-brain

Body-stalk

FIG. 230.—Human embryo between eighteen and twenty-one days old. (His.)

Seventh and Eighth Weeks.—The flexure of the head is gradually reduced and the neck is somewhat lengthened. The upper lip is completed and the nose is more prominent. The nostrils are directed forward and the palate is not completely developed. The eyelids are present in the shape of folds above and below the eye, and the different parts of the auricula are distinguishable. By the end of the second month the fetus measures from 28 to 30 mm. in length (Fig. 234).

Heart

Olfactory

C

FIG. 231.—Human embryo, twenty-seven to thirty days old. (His.)

Third Month.—The head is extended and the neck is lengthened. The eyelids meet and fuse, remaining closed until the end of the sixth month. The limbs are well-developed and nails appear on the digits. The external generative organs are so far differentiated that it is possible to distinguish the sex. By the end of this month the length of the fetus is about 7 cm., but if the legs be included it is from 9 to 10 cm.

Fourth Month.—The loop of gut which projected into the umbilical cord is withdrawn within the fetus. The hairs begin to make their appearance. There is a general increase in size so that by the end of the fourth month the fetus is from 12 to 13 cm. in length, but if the legs be included it is from 16 to 20 cm.

Fifth Month.—It is during this month that the first movements of the fetus are usually observed. The eruption of hair on the head commences, and the *vernix caseosa* begins to be deposited. By the end of this month the total length of the fetus, including the legs, is from 25 to 27 cm.

FIG. 232.—Human embryo, thirty-one to thirty-four days old. (His.)

Sixth Month.—The body is covered by fine hairs (*lanugo*) and the deposit of *vernix caseosa* is considerable. The papillæ of the skin are developed and the free border of the nail projects from the corium of the dermis. Measured from vertex to heels, the total length of the fetus at the end of this month is from 30 to 32 cm.

FIG. 233.—Human embryo of about six weeks. (His.)

FIG. 234.—Human embryo about eight and a half weeks old. (His.)

Seventh Month.—The pupillary membrane atrophies and the eyelids are open. The testis descends with the vaginal sac of the peritoneum. From vertex to heels the total length at the end of the seventh month is from 35 to 36 cm. The weight is a little over three pounds.

Eighth Month.—The skin assumes a pink color and is now entirely coated with vernix caseosa, and the lanugo begins to disappear. Subcutaneous fat has been developed to a considerable extent, and the fetus presents a plump appearance. The total length, *i. e.*, from head to heels, at the end of the eighth month is about 40 cm., and the weight varies between four and one-half and five and one-half pounds.

Ninth Month.—The lanugo has largely disappeared from the trunk. The umbilicus is almost in the middle of the body and the testes are in the scrotum. At full time the fetus weighs from six and one-half to eight pounds, and measures from head to heels about 50 cm.

OSTEOLOGY.

THE general framework of the body is built up mainly of a series of bones, supplemented, however, in certain regions by pieces of cartilage; the bony part of the framework constitutes the **skeleton**.

In comparative anatomy the term skeleton has a wider application, since in some of the lower animals hard, protecting and supporting structures are developed in association with the integumentary system. In such animals the skeleton is described as consisting of an internal or deep skeleton, the **endoskeleton**, and an external or superficial, the **exoskeleton**. In the human subject the exoskeleton is extremely rudimentary, its only important representatives being the nails and the enamel of the teeth. The term skeleton is, therefore, confined to the endoskeleton, and this is divisible into an **axial** part, which includes that of the head and trunk, and an **appendicular** part, which comprises that of the extremities or limbs.

In the skeleton of the adult there are 206 distinct bones, as follows:—

Axial Skeleton	{	Vertebral column	26	
		Skull	22	
		Hyoid bone	1	
		Ribs and sternum	25	
			—	74
Appendicular Skeleton	{	Upper extremities	64	
		Lower extremities	62	
			—	126
Auditory ossicles				6
				—
Total				206

The patellæ are included in this enumeration, but the smaller sesamoid bones are not reckoned.

Bones are divisible into four classes: *Long, Short, Flat, and Irregular*.

Long Bones.—The long bones are found in the limbs, and each consists of a body or shaft and two extremities. The **body**, or **diaphysis** is cylindrical, with a central cavity termed the **medullary canal**; the wall consists of dense, compact tissue of considerable thickness in the middle part of the body, but becoming thinner toward the extremities; within the medullary canal is some cancellous tissue, scanty in the middle of the body but greater in amount toward the ends. The **extremities** are generally expanded, for the purposes of articulation and to afford broad surfaces for muscular attachment. They are usually developed from separate centres of ossification termed **epiphyses**, and consist of cancellous tissue surrounded by thin compact bone. The medullary canal and the spaces in the cancellous tissue are filled with marrow. The long bones are not straight, but curved, the curve generally taking place in two planes, thus affording greater strength to the bone. The bones belonging to this class are: the **clavicle, humerus, radius, ulna, femur, tibia, fibula, metacarpals, metatarsals, and phalanges**.

Short Bones.—Where a part of the skeleton is intended for strength and compactness combined with limited movement, it is constructed of a number of short bones, as in the **carpus** and **tarsus**. These consist of cancellous tissue covered by a thin crust of compact substance. The **patellæ**, together with the other sesamoid bones, are by some regarded as short bones.

Flat Bones.—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, the bones are expanded into broad, flat plates, as in the **skull** and the **scapula**. These bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones, the layers of compact tissue are familiarly known as the **tables of the skull**; the outer one is thick and tough; the inner is thin, dense, and brittle, and hence is termed the **vitreous table**. The intervening cancellous tissue is called the **diploë**, and this, in certain regions of the skull, becomes absorbed so as to leave spaces filled with air (*air-sinuses*) between the two tables. The flat bones are: the **occipital**, **parietal**, **frontal**, **nasal**, **lacrimal**, **vomer**, **scapula**, **os coxæ** (*hip bone*), **sternum**, **ribs**, and, according to some, the **patella**.

Irregular Bones.—The irregular bones are such as, from their peculiar form, cannot be grouped under the preceding heads. They consist of cancellous tissue enclosed within a thin layer of compact bone. The irregular bones are: the **vertebræ**, **sacrum**, **coccyx**, **temporal**, **sphenoid**, **ethmoid**, **zygomatic**, **maxilla**, **mandible**, **palatine**, **inferior nasal concha**, and **hyoid**.

Surfaces of Bones.—If the surface of a bone be examined, certain eminences and depressions are seen. These eminences and depressions are of two kinds: articular and non-articular. Well-marked examples of **articular eminences** are found in the heads of the humerus and femur; and of **articular depressions** in the glenoid cavity of the scapula, and the acetabulum of the hip bone. **Non-articular eminences** are designated according to their form. Thus, a broad, rough, uneven elevation is called a **tuberosity**, **protuberance**, or **process**, a small, rough prominence, a **tubercle**; a sharp, slender pointed eminence, a **spine**; a narrow, rough elevation, running some way along the surface, a **ridge**, **crest**, or **line**. **Non-articular depressions** are also of variable form, and are described as **fossæ**, **pits**, **depressions**, **grooves**, **furrows**, **fissures**, **notches**, etc. These non-articular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well-marked in proportion to the muscularity of the subject; the grooves, fissures, and notches transmit tendons, vessels, or nerves.

The minute structure, growth, and composition of bone are described on pages 50 to 59.

THE VERTEBRAL COLUMN (COLUMNA VERTEBRALIS; SPINAL COLUMN).

The **vertebral column** is a flexuous and flexible column, formed of a series of bones called **vertebræ**.

The **vertebræ** are thirty-three in number, and are grouped under the names **cervical**, **thoracic**, **lumbar**, **sacral**, and **coccygeal**, according to the regions they occupy; there are seven in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or it may be diminished in one region, the deficiency being supplied by an additional vertebra in another. The number of cervical **vertebræ** is, however, very rarely increased or diminished.

The **vertebræ** in the upper three regions of the column remain distinct throughout life, and are known as **true** or **movable** **vertebræ**; those of the sacral and

coccygeal regions, on the other hand, are termed **false** or **fixed** vertebræ, because they are united with one another in the adult to form two bones—five forming the upper bone or **sacrum**, and four the terminal bone or **coccyx**.

With the exception of the first and second cervical, the true or movable vertebræ present certain common characteristics which are best studied by examining one from the middle of the thoracic region.

GENERAL CHARACTERISTICS OF A VERTEBRA.

A **typical vertebra** consists of two essential parts—viz., an anterior segment, the **body**, and a posterior part, the **vertebral** or **neural arch**; these enclose a foramen, the **vertebral foramen**. The vertebral arch consists of a pair of **pedicles** and a pair of **laminae**, and supports **seven processes**—viz., four **articular**, two **transverse**, and one **spinous**.

When the vertebræ are articulated with each other the bodies form a strong pillar for the support of the head and trunk, and the vertebral foramina constitute a canal for the protection of the medulla spinalis (*spinal cord*), while between every pair of vertebræ are two apertures, the **intervertebral foramina**, one on either side, for the transmission of the spinal nerves and vessels.

Body (*corpus vertebrae*).—The body is the largest part of a vertebra, and is more or less cylindrical in shape. Its upper and lower surfaces are flattened and rough, and give attachment to the intervertebral fibrocartilages, and each presents a rim around its circumference. In front, the body is convex from side to side and concave from above downward. Behind, it is flat from above downward and slightly concave from side to side. Its anterior surface presents a few small apertures, for the passage of nutrient vessels; on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of the basi-vertebral veins from the body of the vertebra.

Pedicles (*radices arcu vertebrae*).—The pedicles are two short, thick processes, which project backward, one on either side, from the upper part of the body, at the junction of its posterior and lateral surfaces. The concavities above and below the pedicles are named the **vertebral notches**; and when the vertebræ are articulated, the notches of each contiguous pair of bones form the intervertebral foramina, already referred to.

Laminae.—The laminae are two broad plates directed backward and medialward from the pedicles. They fuse in the middle line posteriorly, and so complete the posterior boundary of the vertebral foramen. Their upper borders and the lower parts of their anterior surfaces are rough for the attachment of the *ligamenta flava*.

Processes.—**Spinous Process** (*processus spinosus*).—The spinous process is directed backward and downward from the junction of the laminae, and serves for the attachment of muscles and ligaments.

Articular Processes.—The articular processes, two superior and two inferior, spring from the junctions of the pedicles and laminae. The superior project upward, and their articular surfaces are directed more or less backward; the inferior project downward, and their surfaces look more or less forward.

Transverse Processes (*processus transversi*).—The transverse processes, two in number, project one at either side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They serve for the attachment of muscles and ligaments.

Structure of a Vertebra (Fig. 235).—The body is composed of cancellous tissue, covered by a thin coating of compact bone; the latter is perforated by numerous orifices, some of large size

for the passage of vessels; the interior of the bone is traversed by one or two large canals, for the reception of veins, which converge toward a single large, irregular aperture, or several small apertures, at the posterior part of the body. The arch and processes projecting from it have thick coverings of compact tissue.

The Cervical Vertebrae (Vertebrae Cervicales).

The **cervical vertebrae** (Fig. 236) are the smallest of the true vertebrae, and can be readily distinguished from those of the thoracic or lumbar regions by the presence of a foramen in each transverse process. The

FIG. 235.—Sagittal section of a lumbar vertebra.

first, second, and seventh present exceptional features and must be separately described; the following characteristics are common to the remaining four.

The **body** is small, and broader from side to side than from before backward. The **anterior and posterior surfaces** are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downward, so as to overlap the upper and forepart of the vertebra below. The **upper surface** is concave transversely, and presents a projecting lip on either side; the **lower surface** is concave from before backward, convex from side to side, and presents laterally shallow concavities which receive the corresponding projecting lips of the subjacent vertebra. The **pedicles** are directed lateralward and backward,

FIG. 236.—A cervical vertebra.

and are attached to the body midway between its upper and lower borders, so that the superior vertebral notch is as deep as the inferior, but it is, at the same time, narrower. The **laminae** are narrow, and thinner above than below; the **vertebral foramen** is large, and of a triangular form. The **spinous process** is short and bifid, the two divisions being often of unequal size. The **superior and inferior articular processes** on either side are fused to form an articular pillar, which projects lateralward from the junction of the pedicle and lamina. The articular facets are flat and of an oval form: the superior look backward, upward, and slightly medialward; the inferior forward, downward, and slightly lateralward. The **transverse processes** are each pierced by the **foramen transversarium**, which, in the upper six vertebrae, gives passage to the vertebral artery and vein and a plexus of sympa-

thetic nerves. Each process consists of an anterior and a posterior part. The **anterior** portion is the homologue of the rib in the thoracic region, and is therefore named the **costal process** or **costal element**: it arises from the side of the body, is directed lateralward in front of the foramen, and ends in a tubercle, the **tuberculum anterius**. The **posterior** part, the true transverse process, springs from the vertebral arch behind the foramen, and is directed forward and lateralward; it ends in a flattened vertical tubercle, the **tuberculum posterius**. These two parts are joined, outside the foramen, by a bar of bone which exhibits a deep sulcus on its upper surface for the passage of the corresponding spinal nerve.¹

Chassaignac first pointed out that the common carotid artery can be easily compressed against the anterior tubercle of the transverse process of the sixth cervical vertebra, and therefore this tubercle is named the *tuberculum caroticum* or *Chassaignac's tubercle*. It also constitutes an important guide to the vertebral artery which enters the foramen transversarium of this vertebra.

FIG. 237.—First cervical vertebra, or atlas.

First Cervical Vertebra.—The first cervical vertebra (Fig. 237) is named the **atlas** because it supports the globe of the head. Its chief peculiarity is that it has no body, and this is due to the fact that the body of the atlas has fused with that of the next vertebra. Its other peculiarities are that it has no spinous process, is ring-like, and consists of an anterior and a posterior arch and two lateral masses. The **anterior arch** forms about one-fifth of the ring: its anterior surface is convex, and presents at its centre the **anterior tubercle** for the attachment of the Longus colli muscles; posteriorly it is concave, and marked by a smooth, oval or circular facet (*fovea dentis*), for articulation with the odontoid process (*dens*) of the axis. The upper and lower borders respectively give attachment to the anterior atlanto-occipital membrane and the anterior atlantoaxial ligament; the former connects it with the occipital bone above, and the latter with the axis below. The **posterior arch** forms about two-fifths of the circumference of the ring: it ends behind in the **posterior tubercle**, which is the rudiment of a spinous process and gives origin to the Recti capitis posteriores minores. The diminutive size of this process prevents any interference with the movements between the atlas and the skull. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior atlantoöccipital membrane, while immediately behind each superior articular process is a groove (*sulcus arteriae vertebralis*), sometimes converted into a foramen by a delicate bony spiculum which arches backward from the posterior end of the superior articular process. This groove represents the superior vertebral notch, and serves for the transmission of the vertebral artery, which, after ascending through the foramen in the transverse

¹ The *costal element* of a cervical vertebra not only includes the portion which springs from the side of the body, but the anterior and posterior tubercles and the bar of bone which connects them (Fig. 97).

process, winds around the lateral mass in a direction backward and medialward; it also transmits the suboccipital (first spinal) nerve. On the under surface of the posterior arch, behind the articular facets, are two shallow grooves, the **inferior vertebral notches**. The lower border gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The **lateral masses** are the most bulky and solid parts of the atlas, in order to support the weight of the head. Each carries two articular facets, a superior and an inferior. The **superior facets** are of large size, oval, concave, and approach each other in front, but diverge behind: they are directed upward, medialward, and a little backward, each forming a cup for the corresponding condyle of the occipital bone, and are admirably adapted to the nodding movements of the head. Not infrequently they are partially subdivided by indentations which encroach upon their margins. The **inferior articular facets** are circular in form, flattened or slightly convex and directed downward and medialward, articulating with the axis, and permitting the rotatory movements of the head. Just below the medial margin of each superior facet is a small tubercle, for the attachment of the transverse atlantal ligament which stretches across the ring of the atlas and divides the vertebral foramen into two unequal parts—the anterior or smaller receiving the odontoid process of the axis, the posterior transmitting the medulla spinalis and its membranes. This part of the vertebral canal is of considerable size, much greater than is required for the accommodation of the medulla spinalis, and hence lateral displacement of the atlas may occur without compression of this structure. The **transverse processes** are large; they project lateralward and downward from the lateral masses, and serve for the attachment of muscles which assist in rotating the head. They are long, and their anterior and posterior tubercles are fused into one mass; the foramen transversarium is directed from below, upward and backward.

Body

Spinous

Inferior articular process

FIG. 238.—Second cervical vertebra, epistropheus, or axis.

Second Cervical Vertebra.—The second cervical vertebra (Fig. 238) is named the **epistropheus** or **axis** because it forms the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive characteristic of this bone is the strong odontoid process which rises perpendicularly from the upper surface of the body. The **body** is deeper in front than behind, and prolonged downward anteriorly so as to overlap the upper and fore part of the third vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions for the attachment of the Longus colli muscles. Its under surface is concave from before backward and convex from side to side. The **dens** or **odontoid process** exhibits a slight constriction or neck, where it joins the body. On its anterior surface is an oval or nearly circular facet for articulation with that on the anterior arch

of the atlas. On the back of the neck, and frequently extending on to its lateral surfaces, is a shallow groove for the transverse atlantal ligament which retains the process in position. The **apex** is pointed, and gives attachment to the middle alar ligament; below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the lateral alar ligament; these ligaments connect the process to the occipital bone. The internal structure of the odontoid process is more compact than that of the body. The **pedicles** are broad and strong, especially in front, where they coalesce with the sides of the body and the root of the odontoid process. They are covered above by the superior articular surfaces. The **laminae** are thick and strong, and the vertebral foramen large, but smaller than that of the atlas. The **transverse processes** are very small, and each ends in a single tubercle; each is perforated by the foramen transversarium, which is directed obliquely upward and lateralward. The **superior articular surfaces** are round, slightly convex, directed upward and lateralward, and are supported on the body, pedicles, and transverse processes. The **inferior articular surfaces** have the same direction as those of the other cervical vertebræ. The **superior vertebral notches** are very shallow, and lie behind the articular processes; the **inferior** lie in front of the articular processes, as in the other cervical vertebræ. The **spinous process** is large, very strong, deeply channelled on its under surface, and presents a bifid, tuberculated extremity.

The Seventh Cervical Vertebra

(Fig. 239).—The most distinctive characteristic of this vertebra is the existence of a long and prominent spinous process, hence the name **vertebra prominens**. This process is thick, nearly horizontal in direction, not bifurcated, but terminating in a tubercle to which the lower end of the ligamentum nuchae is attached. The **transverse processes** are of considerable size, their posterior roots are large and prominent, while the anterior are small and faintly marked; the upper surface of each has usually a shallow sulcus for the eighth spinal nerve, and its extremity seldom presents more than a trace of bifurcation. The foramen transversarium may be as large as that in the other cervical vertebræ, but is generally smaller on one or both sides; occasionally it is double, sometimes it is absent. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen. Sometimes the anterior root of the transverse process attains a large size and exists as a separate bone, which is known as a **cervical rib**.

|
Spinous process

FIG. 239.—Seventh cervical vertebra.

The Thoracic Vertebræ (Vertebrae Thoracales).

The **thoracic vertebræ** (Fig. 240) are intermediate in size between those of the cervical and lumbar regions; they increase in size from above downward the

upper vertebræ being much smaller than those in the lower part of the region. They are distinguished by the presence of facets on the sides of the bodies for articulation with the heads of the ribs, and facets on the transverse processes of all, except the eleventh and twelfth, for articulation with the tubercles of the ribs.

The **bodies** in the middle of the thoracic region are heart-shaped, and as broad in the antero-posterior as in the transverse direction. At the ends of the thoracic region they resemble respectively those of the cervical and lumbar vertebræ. They are slightly thicker behind than in front, flat above and below, convex from side to side in front, deeply concave behind, and slightly constricted laterally and in front. They present, on either side, two costal demi-facets, one above, near the root of the pedicle, the other below, in front of the inferior vertebral notch; these are covered with cartilage in the recent state, and, when the vertebræ are articulated with one another, form, with the intervening intervertebral fibro-cartilages, oval surfaces for the reception of the heads of the ribs. The **pedicles** are directed backward and slightly upward, and the inferior vertebral notches are of large size, and deeper than in any other region of the vertebral column.

Superio

*Facet for articular
of tubercle of rib*

FIG. 240.—A thoracic vertebra.

The **laminae** are broad, thick, and imbricated—that is to say, they overlap those of subjacent vertebræ like tiles on a roof. The **vertebral foramen** is small, and of a circular form. The **spinous process** is long, triangular on coronal section, directed obliquely downward, and ends in a tuberculated extremity. These processes overlap from the fifth to the eighth, but are less oblique in direction above and below.¹ The **superior articular processes** are thin plates of bone projecting upward from the junctions of the pedicles and laminae; their articular facets are practically flat, and are directed backward and a little lateralward and upward. The **inferior articular processes** are fused to a considerable extent with the laminae, and project but slightly beyond their lower borders; their facets are directed forward and a little medialward and downward. The **transverse processes** arise from the arch behind the superior articular processes and pedicles; they are thick, strong, and of considerable length, directed obliquely backward and lateralward,

¹ In quadrupeds the majority of the spinous processes of the thoracic vertebræ project upward and backward, while those of the lumbar region are directed upward and forward. The change in inclination is effected in one of the lower thoracic vertebræ, the spine of which points almost directly upward. This vertebra is known as the *enthinal*, and in man its representative is the eleventh thoracic.

and each ends in a clubbed extremity, on the front of which is a small, concave surface, for articulation with the tubercle of a rib.

The *first, ninth, tenth, eleventh, and twelfth* thoracic vertebræ present certain peculiarities, and must be specially considered (Fig. 241).

FIG. 241.—Peculiar thoracic vertebræ.

The **First Thoracic Vertebra** has, on either side of the **body**, an entire articular facet for the head of the first rib, and a demi-facet for the upper half of the head of the second rib. The body is like that of a cervical vertebra, being broad transversely; its upper surface is concave, and lipped on either side. The **superior articular surfaces** are directed upward and backward; the **spinous process** is thick, long, and almost horizontal. The **transverse processes** are long, and the upper vertebral notches are deeper than those of the other thoracic vertebræ.

The **Ninth Thoracic Vertebra** may have no demi-facets below. In some subjects however, it has two demi-facets on either side; when this occurs the tenth has only demi-facets at the upper part.

The **Tenth Thoracic Vertebra** has (except in the cases just mentioned) an entire articular facet on either side, which is placed partly on the lateral surface of the pedicle.

In the **Eleventh Thoracic Vertebra** the body approaches in its form and size to that of the lumbar vertebræ. The articular facets for the heads of the ribs are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the thoracic region. The **spinous process** is short, and nearly horizontal in direction. The **transverse processes** are very short, tuberculated at their extremities, and have no articular facets.

The **Twelfth Thoracic Vertebra** has the same general characteristics as the eleventh, but may be distinguished from it by its inferior articular surfaces being convex and directed lateralward, like those of the lumbar vertebræ; by the general form of the body, laminæ, and spinous process, in which it resembles the lumbar vertebræ; and by each transverse process being subdivided into three elevations, the superior, inferior, and lateral tubercles: the superior and inferior correspond to the mamillary and accessory processes of the lumbar vertebræ. Traces of similar elevations are found on the transverse processes of the tenth and eleventh thoracic vertebræ.

Superior art

FIG. 242.—A lumbar vertebra seen from the side.

The Lumbar Vertebræ (*Vertebræ Lumbales*).

The lumbar vertebræ (Figs. 242 and 243) are the largest segments of the movable part of the vertebral column, and can be distinguished by the absence of a foramen in the transverse process, and by the absence of facets on the sides of the body.

The **body** is large, wider from side to side than from before backward, and a little thicker in front than behind. It is flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the sides. The **pedicles** are very strong, directed backward from the upper part of the body; consequently, the inferior vertebral notches are of considerable depth. The **laminæ** are broad, short, and strong; the **vertebral foramen** is triangular, larger than in the thoracic, but smaller than in the cervical region. The **spinous process** is thick, broad, and somewhat quadrilateral; it projects backward and ends in a rough, uneven border, thickest below where it is occasionally notched. The **superior and inferior articular processes** are well-defined, projecting respectively upward and downward from the junctions of pedicles and laminæ. The facets

on the superior processes are concave, and look backward and medialward; those on the inferior are convex, and are directed forward and lateralward. The former are wider apart than the latter, since in the articulated column the inferior articular processes are embraced by the superior processes of the subjacent vertebra. The **transverse processes** are long, slender, and horizontal in the upper three lumbar vertebræ; they incline a little upward in the lower two. In the upper three vertebræ they arise from the junctions of the pedicles and laminae, but in the lower two they are set farther forward and spring from the pedicles and posterior parts of the bodies. They are situated in front of the articular processes instead of behind them as in the thoracic vertebræ, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the lower thoracic

FIG. 243.—A lumbar vertebra viewed obliquely from above.

vertebræ, the superior one is connected in the lumbar region with the back part of the superior articular process, and is named the **mamillary process**; the inferior is situated at the back part of the base of the transverse process, and is called the **accessory process** (Fig. 243). Although in man these are comparatively small, in some animals they attain considerable size, and serve to lock the vertebræ more closely together.

The **Fifth Lumbar Vertebra** is characterized by its body being much deeper in front than behind, which accords with the prominence of the sacrovertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articular processes; and by the thickness of its transverse processes, which spring from the body as well as from the pedicles.

The Sacral and Coccygeal Vertebræ.

The **sacral and coccygeal vertebræ** consist at an early period of life of nine separate segments which are united in the adult, so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Sometimes the coccyx consists of five bones; occasionally the number is reduced to three.

The Sacrum (*os sacrum*).—The sacrum is a large, triangular bone, situated in the lower part of the vertebral column and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two hip bones; its upper part or base articulates with the last lumbar vertebra, its apex with the coccyx. It is curved upon itself and placed very obliquely, its base projecting forward and forming the **prominent sacrovertebral angle** when articulated with the last lumbar vertebra; its central part is projected backward, so as to give increased capacity to the pelvic cavity. The sacrum is rather narrower at the level of the second segment than at the level of the third. It presents for examination a pelvic, a dorsal, and two lateral surfaces, a base, an apex, and a central canal.

FIG. 244.

FIG. 244.—Sacrum, pelvic surface.

Pelvic Surface (*facies pelvina*).—The pelvic surface (Fig. 244) is concave from above downward, and slightly so from side to side. Its middle part is crossed by four **transverse ridges**, the positions of which correspond with the original planes of separation between the five segments of the bone. The portions of bone intervening between the ridges are the bodies of the sacral vertebræ. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish from above downward, are flattened from before backward, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At the ends of the ridges are seen the **anterior sacral foramina**, four in number on either side, somewhat rounded in form diminishing in size from above downward, and directed lateralward and forward; they give exit to the anterior divisions of the sacral nerves and entrance to the lateral sacral arteries. Lateral to these foramina are the **lateral parts of the sacrum**, each consisting of five separate segments at an early period of life; in the adult,

these are blended with the bodies and with each other. Each lateral part is traversed by four broad, shallow grooves, which lodge the anterior divisions of the sacral nerves, and are separated by prominent ridges of bone which give origin to the Piriformis muscle.

If a sagittal section be made through the centre of the sacrum (Fig. 246), the bodies are seen to be united at their circumferences by bone, wide intervals being left centrally, which, in the recent state, are filled by the intervertebral fibro-cartilages. In some bones this union is more complete between the lower than the upper segments.

FIG. 245.—Sacrum, dorsal surface

Dorsal Surface (*facies dorsalis*).—The dorsal surface (Fig. 245) is convex and narrower than the pelvic. In the middle line it displays a crest, the **middle sacral crest**, surmounted by three or four tubercles, the rudimentary spinous processes of the upper three or four sacral vertebræ. On either side of the middle sacral crest is a shallow groove, the **sacral groove**, which gives origin to the Multifidus, the floor of the groove being formed by the united laminæ of the corresponding vertebræ. The laminæ of the fifth sacral vertebra, and sometimes those of the fourth, fail to meet behind, and thus a **hiatus** or deficiency occurs in the posterior wall of the sacral canal. On the lateral aspect of the sacral groove is a linear series of tubercles produced by the fusion of the articular processes which together form the indistinct **sacral articular crests**. The articular processes of the first sacral vertebra are large and oval in shape; their facets are concave from side to side, look backward and medialward, and articulate with the facets on the inferior processes of the fifth lumbar vertebra. The tubercles which represent the inferior articular processes of the fifth sacral vertebra are prolonged downward as rounded processes, which are named the **sacral cornua**, and are connected to the cornua

of the coccyx. Lateral to the articular processes are the four **posterior sacral foramina**; they are smaller in size and less regular in form than the anterior, and transmit the posterior divisions of the sacral nerves. On the lateral side of the posterior sacral foramina is a series of tubercles, which represent the transverse processes of the sacral vertebræ, and form the **lateral crests** of the sacrum. The transverse tubercles of the first sacral vertebra are large and very distinct; they, together with the transverse tubercles of the second vertebra, give attachment to the horizontal parts of the posterior sacroiliac ligaments; those of the third vertebra give attachment to the oblique fasciculi of the posterior sacroiliac ligaments; and those of the fourth and fifth to the sacrotuberous ligaments.

Lateral Surface.—The lateral surface is broad above, but narrowed into a thin edge below. The upper half presents in front an ear-shaped surface, the **auricular surface** for articulation with the ilium. Behind it is a rough surface, the **sacral tuberosity**, on which are three deep and uneven impressions, for the attachment of the posterior sacroiliac ligament. The lower half is thin, and ends in a projection called the **inferior lateral angle**; medial to this angle is a notch, which is converted into a foramen by the transverse process of the first piece of the coccyx, and transmits the anterior division of the fifth sacral nerve. The thin lower half of the lateral surface gives attachment to the sacrotuberous and sacrospinous ligaments, to some fibres of the Glutæus maximus behind, and to the Coccygeus in front.

Base (*basis oss. sacri*).—The base of the sacrum, which is broad and expanded, is directed upward and forward. In the middle is a large oval articular surface, the upper surface of the body of the first sacral vertebra, which is connected with the under surface of the body of the last lumbar vertebra by an intervertebral fibrocartilage. Behind this is the large triangular orifice of the sacral canal, which is completed by the laminæ and spinous process of the first sacral vertebra. The superior articular processes project from it on either side; they are oval, concave, directed backward and medialward, like the superior articular processes of a lumbar vertebra. They are attached to the body of the first sacral vertebra and to the alæ by short thick pedicles; on the upper surface of each pedicle is a vertebral notch, which forms the lower part of the foramen between the last lumbar and first sacral vertebræ. On either side of the body is a large triangular surface, which supports the Psoas major and the lumbosacral trunk, and in the articulated pelvis is continuous with the iliac fossa. This is called the **ala**; it is slightly concave from side to side, convex from before backward, and gives attachment to a few of the fibres of the Iliacus. The posterior fourth of the ala represents the transverse process, and its anterior three-fourths the costal process of the first sacral segment.

Apex (*apex oss. sacri*).—The apex is directed downward, and presents an oval facet for articulation with the coccyx.

Vertebral Canal (*canalis sacralis; sacral canal*).—The vertebral canal (Fig. 246) runs throughout the greater part of the bone; above, it is triangular in form; below, its posterior wall is incomplete, from the non-development of the laminæ and spinous processes. It lodges the sacral nerves, and its walls are perforated by the anterior and posterior sacral foramina through which these nerves pass out.

Structure.—The sacrum consists of cancellous tissue enveloped by a thin layer of compact bone.

Articulations.—The sacrum articulates with four bones; the last lumbar vertebra above, the coccyx below, and the hip bone on either side.

Differences in the Sacrum of the Male and Female.—In the female the sacrum is shorter and wider than in the male; the lower half forms a greater angle with the upper; the upper half is nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backward; this increases the size of the pelvic cavity and renders the sacrovertebral angle more prominent. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Variations.—The sacrum, in some cases, consists of six pieces; occasionally the number is reduced to four. Sometimes the uppermost transverse tubercles are not joined to the rest of the ala on one or both sides, or the sacral canal may be open throughout a considerable part of its length, in consequence of the imperfect development of the laminæ and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature.

FIG. 247.—Coccyx.

The Coccyx (*os coccygis*).—The coccyx (Fig. 247) is usually formed of four rudimentary vertebræ; the number may however be increased to five or diminished to three. In each of the first three segments may be traced a rudimentary body and articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone. All the segments are destitute of pedicles, laminæ, and spinous processes. The first is the largest; it resembles the lowest sacral vertebra, and often exists as a separate piece; the last three diminish in size from above downward, and are usually fused with one another. Owing to the gradual diminution in the size of the segments, the coccyx is triangular in form, and presents for examination an anterior and a posterior surface, two borders, a base, and an apex.

Surfaces.—The **anterior surface** is slightly concave, and marked with three transverse grooves which indicate the junctions of the different segments. It gives attachment to the anterior sacrococcygeal ligament and the Levatores ani, and supports part of the rectum. The **posterior surface** is convex, marked by transverse grooves similar to those on the anterior surface, and presents on either side a linear row of tubercles, the rudimentary articular processes of the coccygeal vertebræ. Of these, the superior pair are large, and are called the **coccygeal cornua**; they

project upward, and articulate with the cornua of the sacrum, and on either side complete the foramen for the transmission of the posterior division of the fifth sacral nerve.

Borders.—The lateral borders are thin, and exhibit a series of small eminences, which represent the transverse processes of the coccygeal vertebræ. Of these, the first is the largest; it is flattened from before backward, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downward, and are often wanting. The borders of the coccyx are narrow, and give attachment on either side to the sacrotuberous and sacrospinous ligaments, to the Coccygeus in front of the ligaments, and to the Glutæus maximus behind them.

Base.—The base presents an oval surface for articulation with the sacrum.

Apex.—The apex is rounded, and has attached to it the tendon of the Sphincter ani externus. It may be bifid, and is sometimes deflected to one or other side.

Ossification of the Vertebral Column.—Each vertebra is ossified from three primary centres (Fig. 248), two for the vertebral arch and one for the body.¹ Ossification of the vertebral arches begins in the upper cervical vertebræ about the seventh or eighth week of fetal life, and gradually extends down the column. The ossific granules first appear in the situations where the transverse processes afterward project, and spread backward to the spinous process forward into the pedicles, and lateralward into the transverse and articular processes. Ossification of the bodies begins about the eighth week in the lower thoracic region, and subsequently extends upward and downward along the column. The centre for the body does not give rise to the whole of the body of the adult vertebra, the postero-lateral portions of which are ossified by extensions from the vertebral arch centres. The body of the vertebra during the first few years of life shows, therefore, two synchondroses, **neurocentral synchondroses**, traversing it along the planes of junction of the three centres (Fig. 249). In the thoracic region, the facets for the heads of the ribs lie behind the neurocentral synchondroses and are ossified from the centres for the vertebral arch. At birth the vertebra consists of three pieces, the body and the halves of the vertebral arch. During the first year the halves of the arch unite behind, union taking place first in the lumbar region and then extending upward through the thoracic and cervical regions. About the third year the bodies of the upper cervical vertebræ are joined to the arches on either side; in the lower lumbar vertebræ the union is not completed until the sixth year. Before puberty, no other changes occur, excepting a gradual increase of these primary centres, the upper and under surfaces of the bodies and the ends of the transverse and spinous processes being cartilaginous. About the sixteenth year (Fig. 249), five secondary centres appear, one for the tip of each transverse process, one for the extremity of the spinous process, one for the upper and one for the lower surface of the body (Fig. 250). These fuse with the rest of the bone about the age of twenty-five.

Exceptions to this mode of development occur in the first, second, and seventh cervical vertebræ, and in the lumbar vertebræ.

Atlas.—The atlas is usually ossified from *three* centres (Fig. 251). Of these, one appears in each lateral mass about the seventh week of fetal life, and extends backward; at birth, these portions of bone are separated from one another behind by a narrow interval filled with cartilage. Between the third and fourth years they unite either directly or through the medium of a separate centre developed in the cartilage. At birth, the anterior arch consists of cartilage; in this a separate centre appears about the end of the first year after birth, and joins the lateral masses from the sixth to the eighth year—the lines of union extending across the anterior portions of the superior articular facets. Occasionally there is no separate centre, the anterior arch being formed by the forward extension and ultimate junction of the two lateral masses; sometimes this arch is ossified from two centres, one on either side of the middle line.

Epistropheus or Axis.—The axis is ossified from *five* primary and *two* secondary centres (Fig. 252). The body and vertebral arch are ossified in the same manner as the corresponding parts in the other vertebræ, viz., one centre for the body, and two for the vertebral arch. The centres for the arch appear about the seventh or eighth week of fetal life, that for the body about the fourth or fifth month. The dens or odontoid process consists originally of a continuation upward of the cartilaginous mass, in which the lower part of the body is formed. About the sixth month of fetal life, two centres make their appearance in the base of this process: they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval

¹ A vertebra is occasionally found in which the body consists of two lateral portions—a condition which proves that the body is sometimes ossified from two primary centres, one on either side of the middle line.

between the sides of the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage. The base of the process is separated from the body by a cartilaginous disk, which

gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age. In this cartilage, rudiments of the lower epiphysal lamella of the atlas and the upper epiphysal lamella of the axis may sometimes be found. The apex of the odontoid process has a separate centre which appears in the second and joins about the twelfth year; this is the upper epiphysal lamella of the atlas. In addition to these there is a secondary centre for a thin epiphysal plate on the under surface of the body of the bone.

FIG. 256.—Ossification of the sacrum.

The Seventh Cervical Vertebra.—The anterior or costal part of the transverse process of this vertebra is sometimes ossified from a separate centre which appears about the sixth month of

fetal life, and joins the body and posterior part of the transverse process between the fifth and sixth years. Occasionally the costal part persists as a separate piece, and, becoming lengthened lateralward and forward, constitutes what is known as a *cervical rib*. Separate ossific centres have also been found in the costal processes of the fourth, fifth, and sixth cervical vertebrae.

Lumbar Vertebrae.—The lumbar vertebrae (Fig. 253) have each *two* additional centres, for the mamillary processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently ununited with the rest of the bone, thus forming a lumbar rib—a peculiarity, however, rarely met with.

Sacrum (Figs. 254 to 257).—The *body* of each sacral vertebra is ossified from a primary centre and *two* epiphysal plates, one for its upper and another for its under surface, while each vertebral arch is ossified from two centres.

The anterior portions of the *lateral parts* have *six* additional centres, two for each of the first three vertebrae; these represent the costal elements, and make their appearance above and lateral to the anterior sacral foramina (Figs. 254, 255).

On each *lateral surface* two epiphysal plates are developed (Figs. 256, 257): one for the auricular surface, and another for the remaining part of the thin lateral edge of the bone.¹

PERIODS OF OSSIFICATION.—About the eighth or ninth week of fetal life, ossification of the central part of the body of the first sacral vertebra commences, and is rapidly followed by deposit

FIG. 257.—Base of young sacrum.

of ossific matter in the second and third; ossification does not commence in the bodies of the lower two segments until between the fifth and eighth months of fetal life. Between the sixth and eighth months ossification of the vertebral arches takes place; and about the same time the costal centres for the lateral parts make their appearance. The junctions of the vertebral arches with the bodies take place in the lower vertebrae as early as the second year, but are not effected in the uppermost until the fifth or sixth year.

About the sixteenth year the epiphysal plates for the upper and under surfaces of the bodies are formed; and between the eighteenth and twentieth years, those for the lateral surfaces make their appearance. The bodies of the sacral vertebrae are, during early life, separated from each other by intervertebral fibrocartilages, but about the eighteenth year the two lowest segments become united by bone, and the process of bony union gradually extends upward, with the result that between the twenty-fifth and thirtieth years of life all the segments are united. On examining a sagittal section of the sacrum, the situations of the intervertebral fibrocartilages are indicated by a series of oval cavities (Fig. 246).

Coccyx.—The coccyx is ossified from *four* centres, one for each segment. The ossific nuclei make their appearance in the following order: in the first segment between the first and fourth years; in the second between the fifth and tenth years; in the third between the tenth and fifteenth years; in the fourth between the fourteenth and twentieth years. As age advances, the segments unite with one another, the union between the first and second segments being frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in females, the coccyx often fuses with the sacrum.

THE VERTEBRAL COLUMN AS A WHOLE.

The vertebral column is situated in the median line, as the posterior part of the trunk; its average length in the male is about 71 cm. Of this length the cervical part measures 12.5 cm., the thoracic about 28 cm., the lumbar 18 cm., and the sacrum and coccyx 12.5 cm. The female column is about 61 cm. in length.

Curves.—Viewed laterally (Fig. 258), the vertebral column presents several curves, which correspond to the different regions of the column, and are called cervical, thoracic, lumbar, and pelvic. The **cervical** curve, convex forward, begins

¹ The ends of the spinous processes of the upper three sacral vertebrae are sometimes developed from separate epiphyses, and Fawcett (*Anatomischer Anzeiger*, 1907, Band xxx) states that a number of epiphysal nodules may be seen in the sacrum at the age of eighteen years. These are distributed as follows: One for each of the mamillary processes of the first sacral vertebra; twelve—six on either side—in connection with the costal elements (two each for the first and second and one each for the third and fourth) and eight for the transverse processes—four on either side—one each for the first, third, fourth, and fifth. He is further of opinion that the lower part of each lateral surface of the sacrum is formed by the extension and union of the third and fourth "costal" and fourth and fifth "transverse" epiphyses.

at the apex of the odontoid process, and ends at the middle of the second thoracic vertebra; it is the least marked of all the curves. The **thoracic** curve, concave forward, begins at the middle of the second and ends at the middle of the twelfth thoracic vertebra. Its most prominent point behind corresponds to the spinous process of the seventh thoracic vertebra. The **lumbar** curve is more marked in the female than in the male; it begins at the middle of the last thoracic vertebra, and ends at the sacrovertebral angle. It is convex anteriorly, the convexity of the lower three vertebræ being much greater than that of the upper two. The **pelvic** curve begins at the sacrovertebral articulation, and ends at the point of the coccyx; its concavity is directed downward and forward. The thoracic and pelvic curves are termed **primary** curves, because they alone are present during fetal life. The cervical and lumbar curves are compensatory or secondary, and are developed after birth, the former when the child is able to hold up its head (at three or four months), and to sit upright (at nine months), the latter at twelve or eighteen months, when the child begins to walk.

The vertebral column has also a slight **lateral** curvature, the convexity of which is directed toward the right side. This may be produced by muscular action, most persons using the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation it has been found that in one or two individuals who were left-handed, the convexity was to the left side. By others this curvature is regarded as being produced by the aortic arch and upper part of the descending thoracic aorta—a view which is supported by the fact that in cases where the viscera are transposed and the aorta is on the right side, the convexity of the curve is directed to the left side.

Surfaces. — **Anterior Surface.** — When viewed from in front, the width of the bodies of the vertebræ is seen to increase from the second cervical to the first thoracic; there is then a slight diminution in the next three vertebræ; below this there is again a gradual and progressive increase in width

or Axis*

1st

1st

FIG. 238.—Lateral view of the vertebral column.

as low as the sacrovertebral angle. From this point there is a rapid diminution, to the apex of the coccyx.

Posterior Surface.—The posterior surface of the vertebral column presents in the median line the spinous processes. In the cervical region (with the exception of the second and seventh vertebræ) these are short and horizontal, with bifid extremities. In the upper part of the thoracic region they are directed obliquely downward; in the middle they are almost vertical, and in the lower part they are nearly horizontal. In the lumbar region they are nearly horizontal. The spinous processes are separated by considerable intervals in the lumbar region, by narrower intervals in the neck, and are closely approximated in the middle of the thoracic region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the vertebral column. On either side of the spinous processes is the **vertebral groove** formed by the laminæ in the cervical and lumbar regions, where it is shallow, and by the laminæ and transverse processes in the thoracic region, where it is deep and broad; these grooves lodge the deep muscles of the back. Lateral to the vertebral grooves are the articular processes, and still more laterally the transverse processes. In the thoracic region, the transverse processes stand backward, on a plane, considerably behind that of the same processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed in front of the articular processes, lateral to the pedicles and between the intervertebral foramina. In the thoracic region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar region they are in front of the articular processes, but behind the intervertebral foramina.

Lateral Surfaces.—The lateral surfaces are separated from the posterior surface by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. They present, in front, the sides of the bodies of the vertebræ, marked in the thoracic region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the vertebral notches, oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar. They transmit the spinal nerves and are situated between the transverse processes in the cervical region, and in front of them in the thoracic and lumbar regions.

Base.—The base of that portion of the vertebral column which is made up of the twenty-four movable vertebræ is formed by the under surface of the body of the fifth lumbar vertebræ; and the **summit**, by the upper surface of the atlas.

Vertebral Canal.—The vertebral canal follows the different curves of the column; it is large and triangular in those parts of the column which enjoy the greatest freedom of movement, viz., the cervical and lumbar regions; and is small and rounded in the thoracic region, where motion is more limited.

Applied Anatomy.—Occasionally the coalescence of the laminæ is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (*dura mater* and *arachnoid*), and generally of the *medulla spinalis* itself, takes place, constituting the malformation known as *spina bifida*. This condition is most common in the lumbosacral region, but it may occur in the thoracic or cervical region, or the arches throughout the whole length of the canal may remain incomplete.

The construction of the movable part of the vertebral column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, but permitting of a very considerable range as a whole, allows a sufficient degree of mobility without any material diminution of strength. The many joints of which the column is composed, together with the very varied movements to which it is subjected, render it liable to sprains; but, so closely are the individual vertebræ articulated that these sprains are rarely severe, and an amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its slight liability to

injury are provided for by its disposition in curves instead of in a straight line. For it is an elastic column, and must bend before it breaks; under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one that is equal to it in breadth and material. Again, the safety of the column is largely provided for by the presence between the bodies of the intervertebral fibrocartilages, which act as buffers in counteracting the effects of violent jars or shocks.

Fracture dislocation of the vertebral column may be caused by direct or indirect violence. Fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, while the arches are torn asunder; in fracture from direct violence, on the other hand, the arches are compressed and the bodies of the vertebræ separated from each other. It will therefore be seen that in both classes of injury the medulla spinalis is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. When a fracture dislocation is produced by indirect violence, the displacement is almost always the same; the upper segment being driven forward on the lower, so that the medulla spinalis is compressed between the body of the vertebra below and the arch of the vertebra above.

Diseases of the Vertebral Column.—Spinal caries, or tuberculous disease affecting the cancellous tissue of the bodies of the vertebræ, is a very common condition. When the bodies, having been destroyed, begin to fall together, the spinous processes are necessarily thrown backward and stand out prominently, especially if the disease affect the thoracic region, which is most commonly the case. The condition then goes by the name of *angular curvature*, and great rigidity of the muscles in the affected region accompanies it. Pressure, by the inflammatory thickenings of the disease, is apt to involve the spinal nerves in the affected region, giving rise to peripheral pains, and if the disease be in the lower thoracic vertebræ the pains are referred to the epigastric or umbilical regions, and often the chief thing complained of is "belly ache." Chronic abscess formation in spinal caries is very frequent, and it nearly always forms in front of the vertebral bodies. When the disease is in the lower thoracic region, the abscess usually tracks down behind the Diaphragma and enters the Psoas sheath, forming the well-known *psaos abscess*, which may present above the inguinal ligament, or may pass beneath it into the thigh. In other cases the abscess takes a backward course between the transverse processes and presents as a *thoracic* or *lumbar abscess*; if the disease affect the cervical region of the vertebral column, a *post-pharyngeal abscess* results.

Lateral curvature of the vertebral column is a common affection in girls who are outgrowing their strength and who sit or stand long at lessons, and is due to the uneven transmission of weight down the column. In addition to the lateral displacement of the spinous processes there is a marked rotation of the bodies of the vertebræ, the displacement of which is far in excess of that of the spinous processes. When the curve is severe and the bones have actually become distorted, the condition is past cure.

Kyphosis is an affection in which there is an increase in the normal thoracic curve, and is due to bending forward of the upper part of the body carrying the weight of the head. It is seen in rickety children, in rapidly growing adolescents, in senile conditions, and in certain diseases, such as osteoarthritis and osteitis deformans. In the senile kyphosis often met with in aged laborers, the head is firmly fixed and bent forward and downward on to the chest, and the vertebral column is curved and rigid. The ribs are immobilized, the chest is flattened antero-posteriorly, and breathing becomes almost entirely abdominal. *Postmortem*, bony ankylosis of the ligaments and capsules of the intervertebral joints is found, with ossification of the ligamenta flava, interspinal and other ligaments.

It may be noted that in marked cases of spinal deformity the trachea and aorta follow closely along the line of a spinal curvature occurring in their vicinity, whereas the œsophagus between the tracheal bifurcation and the stomach often passes like a bowstring across the concavity of the curve.

Lordosis, on the other hand, is an exaggeration of the normal lumbar curve, the trunk being thrown backward. This is always a compensatory curve, and occurs when, from any cause such as pregnancy or tumors, the abdomen is enlarged. It is more strongly marked in cases of disease of the hip-joint where the joint is permanently retained in a flexed position, so that in order to bring the foot down to the ground the pelvis has to be tilted forward, and this is accomplished by an increase of the normal lumbar curve.

Laminectomy.—The operation of laminectomy is performed in cases of pressure on the medulla spinalis, where the continuity of the nerve tracts has not been completely destroyed. It consists of cutting down on and removing the laminæ and spinous processes in the affected region, so as to relieve the medulla spinalis from pressure; but it is useless in cases of complete destruction of this structure. Laminectomy is chiefly performed (1) for fracture dislocation; (2) for localized pressure in cases of spinal caries, the object here being to remove the laminæ against which the medulla spinalis is pressed by the inflammatory mass; and (3) for the removal of tumors growing inside the vertebral canal and compressing the medulla spinalis. If such cases be taken early, very satisfactory results are obtained.

THE THORAX.

The skeleton of the **thorax** or **chest** is an osseo-cartilaginous cage, containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backward, and longer behind than in front. It is somewhat reniform on transverse section on account of the projection of the vertebral bodies into the cavity.

Boundaries.—The **posterior surface** is formed by the twelve thoracic vertebræ and the posterior parts of the ribs. It is convex from above downward, and presents on either side of the middle line a deep groove, in consequence of the lateral and backward direction which the ribs take from their vertebral extremities to their angles. The **anterior surface**, formed by the sternum and costal cartilages, is flattened or slightly convex, and inclined from above downward and forward. The **lateral surfaces** are convex; they are formed by the ribs, separated from each other by the intercostal spaces, eleven in number, which are occupied by the Intercostal muscles and membranes.

The **upper opening** of the thorax is reniform in shape, being broader from side to side than from before backward. It is formed by the first thoracic vertebra behind, the upper margin of the sternum in front, and the first rib on either side. It slopes downward and forward, so that the anterior part of the opening is on a lower level than the posterior. Its antero-posterior diameter is about 5 cm., and its transverse diameter about 10 cm. The **lower opening** is formed by the twelfth thoracic vertebra behind, by the eleventh and twelfth ribs at the sides, and in front by the cartilages of the tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the **subcostal angle**, into the apex of which the xiphoid process projects. The lower opening is wider transversely than from before backward, and slopes obliquely downward and backward, it is closed by the Diaphragma which forms the floor of the thorax.

The thorax of the female differs from that of the male as follows: 1. Its capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third thoracic vertebra, whereas in the male it is on a level with the lower part of the body of the second. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax.

The Sternum (Breast Bone).

The **sternum** (Figs. 259 to 261) is an elongated, flattened bone, forming the middle portion of the anterior wall of the thorax. Its upper end supports the clavicles, and its margins articulate with the cartilages of the first seven pairs of ribs. It consists of three parts, named from above downward, the **manubrium**, the **body** or **gladiolus**, and the **xiphoid process**; in early life the body consists of four segments or *sternebrae*. In its natural position the inclination of the bone is oblique from above, downward and forward. It is slightly convex in front and concave behind; broad above, becoming narrowed at the point where the manubrium joins the body, after which it again widens a little to below the middle of the body, and then narrows to its lower extremity. Its average length in the adult is about 17 cm., and is rather greater in the male than in the female.

Manubrium (*manubrium sterni*).—The manubrium is of a somewhat quadrangular form, broad and thick above, narrow below at its junction with the body.

Surfaces.—Its **anterior surface**, convex from side to side, concave from above downward, is smooth, and affords attachment on either side to the sternal origins of the Pectoralis major and Sternocleidomastoideus. In well-marked bones the ridges limiting the attachments of these muscles are very distinct. Its **posterior**

surface, concave and smooth, affords attachment on either side to the Sternohyoideus and Sternothyreoideus.

Borders.—The **superior border** is the thickest and presents at its centre the **jugular** or **presternal notch**; on either side of the notch is an oval articular surface, directed upward, backward, and lateralward, for articulation with the sternal end of the

STERNOCLEIDOMASTOIDEUS

V.

Fig. 259.

FIG. 259.—Anterior surface of sternum and costal cartilages.

clavicle. The **inferior border**, oval and rough, is covered in a recent state with a thin layer of cartilage, for articulation with the body. The **lateral borders** are each marked above by a depression for the first costal cartilage, and below by a small facet, which, with a similar facet on the upper angle of the body, forms a notch for the reception of the costal cartilage of the second rib. Between the depression

for the first costal cartilage and the demi-facet for the second is a narrow, curved edge, which slopes from above downward and medialward.

Body (*corpus sterni; gladiolus*).—The body, considerably longer, narrower, and thinner than the manubrium, attains its greatest breadth close to the lower end.

Surfaces.—Its **anterior surface** is nearly flat, directed upward and forward, and marked by three transverse ridges which cross the bone opposite the third, fourth, and fifth articular depressions.¹ It affords attachment on either side to the sternal origin of the Pectoralis major. At the junction of the third and fourth pieces of the body is occasionally seen an orifice, the **sternal foramen**, of varying size and form. The **posterior surface**, slightly concave, is also marked by three transverse lines, less distinct, however, than those in front; from its lower part, on either side, the Transversus thoracis takes origin.

FIG. 260.—Posterior surface of sternum.

FIG. 261.—Lateral border of sternum

Borders.—The **superior border** is oval and articulates with the manubrium, the junction of the two forming the **sternal angle** (*angulus Ludovici*²). The **inferior border** is narrow, and articulates with the xiphoid process. Each **lateral border** (Fig. 261), at its superior angle, has a small facet, which with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; below this are four angular depressions which receive the cartilages of the third, fourth, fifth, and sixth ribs, while the inferior angle has a small facet, which, with a corresponding one on the xiphoid process, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downward, and correspond to

¹ Paterson (The Human Sternum, 1904), who examined 524 specimens, points out that these ridges are altogether absent in 26.7 per cent., that in 69 per cent. a ridge exists opposite the third costal attachment, in 39 per cent. opposite the fourth; and in 4 per cent. only, opposite the fifth.

² Named after the French surgeon Antoine Louis, 1723-1792. The Latin name *angulus Ludovici* is not infrequently mistranslated into English as "the angle of Ludwig."

FIG. 262.—Ossification of the sternum.

FIG. 263

FIG. 264.—Peculiarities.

---------------------------------	---

FIG. 265

the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the lines of junction of its primitive component segments. This is well seen in many of the lower animals, where the parts of the bone remain ununited longer than in man.

Xiphoid Process (*processus xiphoideus; ensiform or xiphoid appendix*).—The xiphoid process is the smallest of the three pieces: it is thin and elongated, cartilaginous in structure in youth, but more or less ossified at its upper part in the adult.

Surfaces.—Its **anterior surface** affords attachment on either side to the anterior costoxiphoid ligament and a small part of the Rectus abdominis; its **posterior surface**, to the posterior costoxiphoid ligament and to some of the fibres of the Diaphragma and Transversus thoracis, its **lateral borders**, to the aponeuroses of the abdominal muscles. Above, it articulates with the lower end of the body, and on the front of each superior angle presents a facet for part of the cartilage of the seventh rib; below, by its pointed extremity, it gives attachment to the linea alba. The xiphoid process varies much in form; it may be broad and thin, pointed, bifid, perforated, curved, or deflected considerably to one or other side.

Structure.—The sternum is composed of highly vascular cancellous tissue, covered by a thin layer of compact bone which is thickest in the manubrium between the articular facets for the clavicles.

Ossification.—The sternum originally consists of two cartilaginous bars, situated one on either side of the median plane and connected with the cartilages of the upper nine ribs of its own side. These two bars fuse with each other along the middle line to form the cartilaginous sternum which is ossified from *six* centres: one for the manubrium, four for the body, and one for the xiphoid process (Fig. 262). The ossific centres appear in the intervals between the articular depressions for the costal cartilages, in the following order: in the manubrium and first piece of the body, during the sixth month; in the second and third pieces of the body, during the seventh month of fetal life; in its fourth piece, during the first year after birth; and in the xiphoid process, between the fifth and eighteenth years. The centres make their appearance at the upper parts of the segments, and proceed gradually downward.¹ To these may be added the occasional existence of two small episternal centres, which make their appearance one on either side of the jugular notch; they are probably vestiges of the episternal bone of the monotremata and lizards. Occasionally some of the segments are formed from more than one centre, the number and position of which vary (Fig. 264). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper being the larger; the second piece has seldom more than one; the third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which explains the rare occurrence of the sternal foramen (Fig. 265), or of the vertical fissure which occasionally intersects this part of the bone; these conditions are further explained by the manner in which the cartilaginous sternum is formed. Union of the various centres of the body begins about puberty, and proceeds from below upward (Fig. 263); by the age of twenty-five they are all united. The xiphoid process may become joined to the body before the age of thirty, but this occurs more frequently after forty; on the other hand, it sometimes remains ununited in old age. In advanced life the manubrium is occasionally joined to the body by bone. When this takes place, however, the bony tissue is generally only superficial, the central portion of the intervening cartilage remaining unossified.

Articulations.—The sternum articulates on either side with the clavicle and upper seven costal cartilages.

The Ribs (Costae).

The ribs are elastic arches of bone, which form a large part of the thoracic skeleton. They are twelve in number on either side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the vertebral column, and in front, through the intervention of the costal cartilages, with the sternum (Fig. 259); they are called **true** or **vertebro-sternal ribs**.² The remaining five are **false**

¹ Out of 141 sterna between the time of birth and the age of sixteen years, Paterson (*op. cit.*) found the fourth or lowest centre for the body present only in thirty-eight cases—i. e., 26.9 per cent.

² Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right than on the left side.

neck, and perforated by numerous foramina. Of its two borders the **superior** presents a rough crest (*crista colli costae*) for the attachment of the anterior costotransverse ligament; its **inferior border** is rounded. On the posterior surface at the junction of the neck and body, and nearer the lower than the upper border, is an eminence—the **tubercle**; it consists of an articular and a non-articular portion. The *articular portion*, the lower and more medial of the two, presents a small, oval surface for articulation with the end of the transverse process of the lower of the two vertebræ to which the head is connected. The *non-articular portion* is a rough elevation, and affords attachment to the ligament of the tubercle. The tubercle is much more prominent in the upper than in the lower ribs.

Body.—The **body** or **shaft** is thin and flat, with two surfaces, an external and an internal; and two borders, a superior and an inferior. The **external surface** is convex, smooth, and marked, a little in front of the tubercle, by a prominent line, directed downward and lateralward; this gives attachment to a tendon of the *Iliocostalis*, and is called the **angle**. At this point the rib is bent in two directions, and at the same time twisted on its long axis. If the rib be laid upon its lower border, the portion of the body in front of the angle rests upon this border, while the portion behind the angle is bent medialward and at the same time tilted upward; as the

FIG. 267.—A central rib of the left side, viewed from behind.

result of the twisting, the external surface, behind the angle, looks downward, and in front of the angle, slightly upward. The distance between the angle and the tubercle is progressively greater from the second to the tenth ribs. The portion between the angle and the tubercle is rounded, rough, and irregular, and serves for the attachment of the *Longissimus dorsi*. The external surface presents, toward its sternal end, an oblique line, the **anterior angle**. The **internal surface** is concave, smooth, directed a little upward behind the angle, a little downward in front of it, and is marked by a ridge which commences at the lower extremity of the head; this ridge is strongly marked as far as the angle, and gradually becomes lost at the junction of the anterior and middle thirds of the bone. Between it and the inferior border is a groove, the **costal groove**, for the intercostal vessels and nerve. At the back part of the bone, this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it is on the internal surface. The superior edge of the groove is rounded and serves for the attachment of an *Intercostalis internus*; the inferior edge corresponds to the lower margin of the rib, and gives attachment to an *Intercostalis externus*. Within the groove are seen the orifices of numerous small foramina for nutrient vessels

which traverse the shaft obliquely from before backward. The **superior border**, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front, which serve for the attachment of *Intercostales externus* and *internus*. The **inferior border** is thin, and has attached to it an *Intercostalis externus*.

Anterior Extremity.—The anterior or sternal extremity is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

FIGS. 268 to 272.—Peculiar ribs.

Peculiar Ribs.—The first, second, tenth, eleventh, and twelfth ribs present certain variations from the common characteristics described above, and require special consideration.

First Rib.—The first rib (Fig. 268) is the most curved and usually the shortest of all the ribs; it is broad and flat, its surfaces looking upward and downward, and its borders inward and outward. The **head** is small, rounded, and possesses

only a single articular facet, for articulation with the body of the first thoracic vertebra. The **neck** is narrow and rounded. The **tubercle**, thick and prominent, is placed on the outer border. There is *no angle*, but at the tubercle the rib is slightly bent, with the convexity upward, so that the head of the bone is directed downward. The **upper surface** of the body is marked by two shallow grooves, separated from each other by a slight ridge prolonged internally into a tubercle, the **scalene tubercle**, for the attachment of the *Scalenus anterior*; the anterior groove transmits the subclavian vein, the posterior the subclavian artery and the lowest trunk of the brachial plexus.¹ Behind the posterior groove is a rough area for the attachment of the *Scalenus medius*. The **under surface** is smooth, and destitute of a costal groove. The **outer border** is convex, thick, and rounded, and at its posterior part gives attachment to the first digitation of the *Serratus anterior*; the **inner border** is concave, thin, and sharp, and marked about its centre by the scalene tubercle. The **anterior extremity** is larger and thicker than that of any of the other ribs.

Second Rib.—The second rib (Fig. 269) is much longer than the first, but has a very similar curvature. The non-articular portion of the **tubercle** is occasionally only feebly marked. The **angle** is slight, and situated close to the tubercle. The **body** is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a bend, with its convexity upward, similar to, though smaller than that found in the first rib. The body is not flattened horizontally like that of the first rib. Its **external surface** is convex, and looks upward and a little outward; near the middle of it is a rough eminence for the origin of the lower part of the first and the whole of the second digitation of the *Serratus anterior*; behind and above this is attached the *Scalenus posterior*. The **internal surface**, smooth, and concave, is directed downward and a little inward: on its posterior part there is a short costal groove.

Tenth Rib.—The tenth rib (Fig. 270) has only a single articular facet on its head.

Eleventh and Twelfth Ribs.—The eleventh and twelfth ribs (Figs. 271 and 272) have each a single articular facet on the head, which is of rather large size; they have *no necks or tubercles*, and are pointed at their anterior ends. The eleventh has a slight angle and a shallow costal groove. The twelfth has neither; it is much shorter than the eleventh, and its head is inclined slightly downward. Sometimes the twelfth rib is even shorter than the first.

Structure.—The ribs consist of highly vascular cancellous tissue, enclosed in a thin layer of compact bone.

Ossification.—Each rib, with the exception of the last two, is ossified from *four* centres; a primary centre for the body, and three epiphysal centres; one for the head and one each for the articular and non-articular parts of the tubercle. The eleventh and twelfth ribs have each only *two* centres, those for the tubercles being wanting. Ossification begins near the angle toward the end of the second month of fetal life, and is seen first in the sixth and seventh ribs. The epiphyses for the head and tubercle make their appearance between the sixteenth and twentieth years, and are united to the body about the twenty-fifth year. Fawcett² states that "in all probability there is usually no epiphysis on the non-articular part of the tuberosity below the sixth or seventh rib.

The Costal Cartilages (*Cartilagines Costales*).

The **costal cartilages** (Fig. 259) are bars of hyaline cartilage which serve to prolong the ribs forward and contribute very materially to the elasticity of the walls of the thorax. The first seven pairs are connected with the sternum; the next three are each articulated with the lower border of the cartilage of the preceding rib; the last two have pointed extremities, which end in the wall of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and

¹ Anat. Anzeiger, 1910, Band xxxvi.

² Journal of Anatomy and Physiology, vol. xiv.

direction. They increase in length from the first to the seventh, then gradually decrease to the twelfth. Their breadth, as well as that of the intervals between them, diminishes from the first to the last. They are broad at their attachments to the ribs, and taper toward their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. They also vary in direction: the first descends a little, the second is horizontal, the third ascends slightly, while the others are angular, following the course of the ribs for a short distance, and then ascending to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities.

Surfaces.—The **anterior surface** is convex, and looks forward and upward: that of the first gives attachment to the costoclavicular ligament and the Subclavius muscle; those of the first six or seven at their sternal ends, to the Pectoralis major. The others are covered by, and give partial attachment to, some of the flat muscles of the abdomen. The **posterior surface** is concave, and directed backward and downward; that of the first gives attachment to the Sternothyroideus, those of the third to the sixth inclusive to the Transversus thoracis, and the six or seven inferior ones to the Transversus abdominis and the Diaphragma.

Borders.—Of the two borders the **superior** is concave, the **inferior** convex; they afford attachment to the Intercostales interni: the upper border of the sixth gives attachment also to the Pectoralis major. The inferior borders of the sixth, seventh, eighth, and ninth cartilages present heel-like projections at the points of greatest convexity. These projections carry smooth oblong facets which articulate respectively with facets on slight projections from the upper borders of the seventh, eighth, ninth, and tenth cartilages.

Extremities.—The **lateral end** of each cartilage is continuous with the osseous tissue of the rib to which it belongs. The **medial end** of the first is continuous with the sternum; the medial ends of the six succeeding ones are rounded and are received into shallow concavities on the lateral margins of the sternum. The medial ends of the eighth, ninth, and tenth costal cartilages are pointed, and are connected each with the cartilage immediately above. Those of the eleventh and twelfth are pointed and free. In old age the costal cartilages are prone to undergo superficial ossification.

Applied Anatomy.—Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages which support it like so many springs. The fracture usually occurs in the upper half of the body. Dislocation of the body from the manubrium may take place, and is sometimes described as a fracture.

The bone is frequently the seat of gummatous tumors and not uncommonly is affected with caries.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle ribs are the most liable to fracture. The first and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest wall, and the bone then gives way at its weakest part, *i. e.*, just in front of the angle. But the ribs may also be broken by direct violence, in which case the bone is driven inward at the point struck. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity; this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages or separation of the cartilages from the ribs, may also take place, though they are comparatively rare injuries. In workmen the pressure of tools may displace the xiphoid process inward.

The ribs are frequently the seat of tuberculous disease, with the formation of a chronic abscess in the chest wall. This may not immediately overlies the carious portion of rib, as the pus is often directed a considerable distance along the costal groove before appearing beneath the integument.

Resection of a portion of a rib is often required in order to give efficient drainage to an empyema; this is referred to in the description of the respiratory organs.

Cervical ribs derived from the seventh cervical vertebra (page 201) are of not infrequent occurrence, and are important clinically because they may give rise to obscure nervous or vascular symptoms. The cervical rib may be a mere epiphysis articulating only with the transverse process of the vertebra, but more commonly it consists of a defined head, neck, and tubercle, with or without a body. It extends lateralward, or forward and lateralward, into the posterior triangle of the neck, where it may terminate in a free end or may join the first thoracic rib, the first costal cartilage, or the sternum.¹ It varies much in shape, size, direction, and mobility. If it reach far enough forward, part of the brachial plexus and the subclavian artery and vein cross over it, and are apt to suffer compression in so doing. Pressure on the artery may obstruct the circulation so much that arterial thrombosis results, causing gangrene of the finger tips. Pressure on the nerves is commoner, and affects the eighth cervical and first thoracic nerves, causing paralysis of the muscles they supply, and neuralgic pains and paresthesia in the area of skin to which they are distributed: no oculopupillary changes are to be found. If these symptoms be severe, removal of the rib or as much of it as causes pressure on the vessels and nerves is called for. The operation is not free from difficulty, and has been followed by paralysis of the muscles and by subclavian aneurism, due to injuries inflicted in the course of the operation.

The *thorax* is frequently found to be altered in shape in certain diseases.

In *rickets*, the ends of the ribs, where they join the costal cartilages, become enlarged, giving rise to the so-called "rickety rosary," which in mild cases is only found on the internal surface of the thorax. Lateral to these enlargements the softened ribs sink in, so as to present a groove passing downward and lateralward on either side of the sternum. This bone is forced forward by the bending of the ribs, and the antero-posterior diameter of the chest is increased. The ribs affected are the second to the eighth, the lower ones being prevented from falling in by the presence of the liver, stomach, and spleen; and when the abdomen is distended, as it often is in rickets, the lower ribs may be pushed outward, causing a transverse groove (Harrison's sulcus) just above the costal arch. This deformity or forward projection of the sternum, often asymmetrical, is known as *pigeon breast*, and may be taken as evidence of active or old rickets except in cases of primary spinal curvature. In many instances it is associated in children with obstruction in the upper air passages, due to enlarged tonsils or adenoid growths. In some rickety children or adults, and also in others who give no history or further evidence of having had rickets, an opposite condition obtains. The lower part of the sternum and often the xiphoid process as well are deeply depressed backward, producing an oval hollow in the lower sternal and upper epigastric regions. This is known as *funnel breast* (German, *Trichterbrust*); it never appears to produce the least disturbance of any of the vital functions. The *phthistical chest* is often long and narrow, and with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the *barrel-shaped chest*. In severe cases of *lateral curvature of the vertebral column* the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebrae which takes place in this disease, the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincidentally with this the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind, and bulging and convex in front.

It is commonly said that in tuberculosis of the lungs the chest is characteristically "flat," that is to say, that the ratio of its antero-posterior to its transverse diameter is less than the normal. But by careful measurement in a large number of cases, Woods Hutchinson has shown that this is not so. Taking the transverse diameter of the chest at the nipple level as = 100, he finds that in the normal adult man between the ages of twenty and forty-four the antero-posterior diameter = 71. In 82 phthistical subjects it was = 79.5, and in 30 "flat-chested" persons was = 80. He explains the error as an optical illusion, due to rolling forward of the shoulders in the "flat chested;" the back is seen to be correspondingly rounded and protuberant, while the forward position of the shoulders and clavicles lends an appearance of flattening to the chest.

More or less shrinkage of one side of the thorax is often seen as a consequence of adhesive pleurisy, in which the pulmonary and parietal pleurae adhere closely to one another and the lung becomes collapsed and fibrosed. If this process be at all complete, great deformity of the chest results, the ribs on the affected side falling in, together with obliteration of the intercostal spaces; the contents of the mediastinal cavity are pulled over toward the affected side, the other lung becomes emphysematous compensatorily. The vertebral column becomes scoliotic, with the concavity of the curve toward the affected side.

THE SKULL.

The *skull* is supported on the summit of the vertebral column, and is of an oval shape, wider behind than in front. It is composed of a series of flattened

¹ W. Thorburn, The Medical Chronicle, Manchester, 1907, 4th series, xiv, No. 3.

or irregular bones which, with one exception (the mandible), are immovably jointed together. It is divisible into two parts: (1) the **cranium**, which lodges and protects the brain, consists of eight bones, and (2) the **skeleton of the face**, of fourteen, as follows:

<i>Skull, 22 bones</i>	{	<i>Cranium, 8 bones</i>	{	Occipital.			
				Two Parietals.			
				Frontal.			
				Two Temporals.			
				Sphenoidal.			
				Ethmoidal.			
				{	<i>Face, 14 bones</i>	{	Two Nasals.
							Two Maxillæ.
	Two Lacrimals.						
	Two Zygomatics.						
	Two Palatines.						
	Two Inferior Nasal Conchæ.						
					Vomer.		
					Mandible.		

In the Basle nomenclature, certain bones developed in association with the nasal capsule, viz., the inferior nasal conchæ, the lacrimals, the nasals, and the vomer, are grouped as cranial and not as facial bones.

The hyoid bone, situated at the root of the tongue and attached to the base of the skull by ligaments, is described in this section.

THE CRANIAL BONES (OSSA CRANII).

The Occipital Bone (Os Occipitale).

The **occipital bone** (Figs. 273, 274), situated at the back and lower part of the cranium, is trapezoid in shape and curved on itself. It is pierced by a large oval aperture, the **foramen magnum**, through which the cranial cavity communicate with the vertebral canal.

The curved, expanded plate behind the foramen magnum is named the **squama**; the thick, somewhat quadrilateral piece in front of the foramen is called the **basilar part**, whilst on either side of the foramen is the **lateral portion**.

The Squama (*squama occipitalis*).—The squama, situated above and behind the foramen magnum, is curved from above downward and from side to side.

Surfaces.—The **external surface** is convex and presents midway between the summit of the bone and the foramen magnum a prominence, the **external occipital protuberance**. Extending lateralward from this on either side are two curved lines, one a little above the other. The upper, often faintly marked, is named the **highest nuchal line**, and to it the galea aponeurotica is attached. The lower is termed the **superior nuchal line**. That part of the squama which lies above the highest nuchal lines is named the **planum occipitale**, and is covered by the Occipitalis muscle; that below, termed the **planum nuchale**, is rough and irregular for the attachment of several muscles. From the external occipital protuberance a ridge or crest, the **median nuchal line**, often faintly marked, descends to the foramen magnum, and affords attachment to the ligamentum nuchæ; running from the middle of this line across either half of the nuchal plane is the **inferior nuchal line**. Several muscles are attached to the outer surface of the squama, thus: the superior nuchal line gives origin to the Occipitalis and Trapezius, and insertion

to the Sternocleidomastoideus and Splenius capitis: into the surface between the superior and inferior nuchal lines the Semispinalis capitis and the Obliquus capitis superior are inserted, while the inferior nuchal line and the area below it receive the insertions of the Recti capitis posteriores major and minor. The posterior atlantoöccipital membrane is attached around the postero-lateral part of the foramen magnum, just outside the margin of the foramen.

78

FIG. 273.—Occipital bone. Outer surface.

The **internal surface** is deeply concave and divided into four fossæ by a **cruciate eminence**. The upper two fossæ are triangular and lodge the occipital lobes of the cerebrum; the lower two are quadrilateral and accommodate the hemispheres of the cerebellum. At the point of intersection of the four divisions of the cruciate eminence is the **internal occipital protuberance**. From this protuberance the upper division of the cruciate eminence runs to the superior angle of the bone, and on one side of it (generally the right) is a deep groove, the **sagittal sulcus**, which lodges the hinder part of the superior sagittal sinus; to the margins of this sulcus the falx cerebri is attached. The lower division of the cruciate eminence is prominent, and is named the **internal occipital crest**; it bifurcates near the foramen magnum and gives attachment to the falx cerebelli; in the attached margin of this falx is the occipital sinus, which is sometimes duplicated. In the upper part of the internal occipital crest, a small depression is sometimes distinguishable; it is termed the **vermian fossa** since it is occupied by part of the vermis of the cerebellum. Transverse grooves, one on either side, extend from the internal occipital protuberance to the lateral angles of the bone; those grooves accommodate the transverse sinuses, and their prominent margins give attachment to the tentorium cerebelli. The groove on the right side is usually larger than that on the left, and is

continuous with that for the superior sagittal sinus. Exceptions to this condition are, however, not infrequent; the left may be larger than the right or the two may be almost equal in size. The angle of union of the superior sagittal and transverse sinuses is named the **confluence of the sinuses** (*torcular Herophili*¹), and its position is indicated by a depression situated on one or other side of the protuberance.

Superior Angle

Inferior Angle

FIG. 274.—Occipital bone. Inner surface

Lateral Parts (*pars lateralis*).—The lateral parts are situated at the sides of the foramen magnum; on their under surfaces are the **condyles** for articulation with the superior facets of the atlas. The condyles are oval or reniform in shape, and their anterior extremities, directed forward and medialward, are closer together than their posterior, and encroach on the basilar portion of the bone; the posterior extremities extend back to the level of the middle of the foramen magnum. The articular surfaces of the condyles are convex from before backward and from side to side, and look downward and lateralward. To their margins are attached the capsules of the atlantooccipital articulations, and on the medial side of each is a rough impression or tubercle for the alar ligament. At the base of either condyle the bone is tunnelled by a short canal, the **hypoglossal canal** (*anterior condyloid foramen*). This begins on the cranial surface of the bone immediately above the foramen magnum, and is directed lateralward and forward above

¹ The columns of blood coming in different directions were supposed to be pressed together at this point as wine press).

condyle. It may be partially or completely divided into two by a spicule of bone; it gives exit to the hypoglossal or twelfth cerebral nerve, and entrance to a meningeal branch of the ascending pharyngeal artery. Behind either condyle is a depression, the **condyloid fossa**, which receives the posterior margin of the superior facet of the atlas when the head is bent backward; the floor of this fossa is sometimes perforated by the **condyloid canal**, through which an emissary vein passes from the transverse sinus. Extending lateralward from the posterior half of the condyle is a quadrilateral plate of bone, the **jugular process**, excavated in front by the **jugular notch**, which, in the articulated skull, forms the posterior part of the jugular foramen. The jugular notch may be divided into two by a bony spicule, the **intra-jugular process**, which projects lateralward above the hypoglossal canal. The under surface of the jugular process is rough, and gives attachment to the Rectus capitis lateralis muscle and the lateral atlantooccipital ligament; from this surface an eminence, the **paramastoid process**, sometimes projects downward, and may be of sufficient length to reach, and articulate with, the transverse process of the atlas. Laterally the jugular process presents a rough quadrilateral or triangular area which is joined to the jugular surface of the temporal bone by a plate of cartilage; after the age of twenty-five this plate tends to ossify.

The **upper surface** of the lateral part presents an oval eminence, the **jugular tubercle**, which overlies the hypoglossal canal and is sometimes crossed by an oblique groove for the glossopharyngeal, vagus, and accessory nerves. On the upper surface of the jugular process is a deep groove which curves medialward and forward and is continuous with the jugular notch. This groove lodges the terminal part of the transverse sinus, and opening into it, close to its medial margin, is the orifice of the condyloid canal.

Basilar Part (*pars basilaris*).—The basilar part extends forward and upward from the foramen magnum, and presents *in front* an area more or less quadrilateral in outline. In the young skull this area is rough and uneven, and is joined to the body of the sphenoid by a plate of cartilage. By the twenty-fifth year this cartilaginous plate is ossified, and the occipital and sphenoid form a continuous bone.

Surfaces.—On its **lower surface**, about 1 cm. in front of the foramen magnum, is the **pharyngeal tubercle** which gives attachment to the fibrous raphé of the pharynx. On either side of the middle line the Longus capitis and Rectus capitis anterior are inserted, and immediately in front of the foramen magnum the anterior atlantooccipital membrane is attached.

The **upper surface** presents a broad, shallow groove which inclines upward and forward from the foramen magnum; it supports the medulla oblongata, and near the margin of the foramen magnum gives attachment to the membrana tectoria. On the lateral margins of this surface are faint grooves for the inferior petrosal sinuses.

Foramen Magnum.—The foramen magnum is a large oval aperture with its long diameter antero-posterior; it is wider behind than in front where it is encroached upon by the condyles. It transmits the medulla oblongata and its membranes, the accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the membrana tectoria and alar ligaments.

Angles.—The **superior angle** of the occipital bone articulates with the occipital angles of the parietal bones and, in the fetal skull, corresponds in position with the **anterior fontanelle**. The **inferior angle** is fused with the body of the sphenoid. The **lateral angles** are situated at the extremities of the grooves for the transverse sinuses: each is received into the interval between the mastoid angle of the parietal bone and the mastoid part of the temporal.

Borders.—The **superior borders** extend from the superior to the lateral angles: they are deeply serrated for articulation with the occipital borders of the parietals, and form by this union the **lambdoidal suture**. The **inferior borders** extend from the

the lateral angles to the inferior angle; the upper half of each articulates with the mastoid portion of the corresponding temporal, the lower half with the petrous part of the same bone. These two portions of the inferior border are separated from one another by the jugular process, the notch on the anterior surface of which forms the posterior part of the jugular foramen.

Structure.—The occipital, like the other cranial bones, consists of two compact lamellæ, called the *outer* and *inner tables*, between which is the cancellous tissue or diploë; the bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar part; in the inferior fossæ it is thin, semitransparent, and destitute of diploë.

Ossification (Fig. 275).—The planum occipitale of the squama is developed in membrane, and may remain separate throughout life when it constitutes the *interparietal* bone; the rest of the bone is developed in cartilage. The number of nuclei for the planum occipitale is usually given as four, two appearing near the middle line about the second month, and two some little distance from the middle line about the third month of fetal life. The planum nuchale of the squama is ossified from two centres, which appear about the seventh week of fetal life and soon unite to form a single piece. Union of the upper and lower portions of the squama takes place in the third month of fetal life. An occasional centre (Kerckring) appears in the posterior margin of the foramen magnum during the fifth month; this forms a separate ossicle (sometimes double) which unites with the rest of the squama before birth. Each of the lateral parts begins to ossify from a single centre during the eighth week of fetal life. The basilar portion is ossified from two centres, one in front of the other; these appear about the sixth week of fetal life and rapidly coalesce. Mall¹ states that the planum occipitale is ossified from two centres and the basilar portion from one. About the fourth year the squama and the two lateral portions unite, and about the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the occipital and sphenoid become united, forming a single bone.

FIG. 275.—Occipital bone at birth.

Articulations.—The occipital articulates with *six* bones: the two parietals, the two temporals, the sphenoid, and the atlas.

The Parietal Bone (Os Parietale).

The **parietal bones** form, by their union, the sides and roof of the cranium. Each bone is irregularly quadrilateral in form, and has two surfaces, four borders, and four angles.

Surfaces.—The **external surface** (Fig. 276) is convex, smooth, and marked near the centre by an eminence, the **parietal eminence** (*tuber parietale*), which indicates the point where ossification commenced. Crossing the middle of the bone in an arched direction are two curved lines, the **superior** and **inferior temporal lines**; the former gives attachment to the temporal fascia, and the latter indicates the upper limit of the muscular origin of the Temporalis. Above these lines the bone is covered by the **galea aponeurotica**; below them it forms part of the temporal fossa, and affords attachment to the Temporalis muscle. At the back part and close to the upper or sagittal border is the **parietal foramen**, which transmits a vein to the superior sagittal sinus, and sometimes a small branch of the occipital artery; it is not constantly present, and its size varies considerably.

¹ American Journal of Anatomy, 1906, vol. v.

The **internal surface** (Fig. 277) is concave; it presents depressions corresponding to the cerebral convolutions, and numerous furrows for the ramifications of the middle meningeal vessel;¹ the latter run upward and backward from the sphenoidal angle, and from the central and posterior part of the squamous border. Along the upper margin is a shallow groove, which, together with that on the opposite parietal, forms a channel, the **sagittal sulcus**, for the superior sagittal sinus; the edges of the sulcus afford attachment to the falx cerebri. Near the groove are several depressions, best marked in the skulls of old persons, for the **arachnoid granulations** (*Pacchionian bodies*). In the groove is the internal opening of the parietal foramen when that aperture exists.

FIG. 276.—Left parietal bone. Outer surface.

Borders.—The **sagittal border**, the longest and thickest, is dentated and articulates with its fellow of the opposite side, forming the sagittal suture. The **squamous border** is divided into three parts; of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squama of the temporal; the posterior part is thick and serrated for articulation with the mastoid portion of the temporal. The **frontal border** is deeply serrated, and bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming one-half of the **coronal suture**. The **occipital border**, deeply denticulated, articulates with the occipital, forming one-half of the **lambdoidal suture**.

¹ Journal of Anatomy and Physiology, 1912, vol. xvi.

Angles.—The **frontal angle** is practically a right angle, and corresponds with the point of meeting of the sagittal and coronal sutures; this point is named the **bregma**; in the fetal skull and for about a year and a half after birth this region is membranous, and is called the **anterior fontanelle**. The **sphenoidal angle**, thin and acute, is received into the interval between the frontal bone and the great wing of the sphenoid. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior divisions of the middle meningeal artery. The **occipital angle** is rounded and corresponds with the point of meeting of the sagittal and lambdoidal sutures—a point which is termed the **lambda**; in the fetus this part of the skull is membranous, and is called the **posterior fontanelle**. The **mastoid angle** is truncated; it articulates with the occipital bone and with the mastoid portion of the temporal, and presents on its inner surface a broad, shallow groove which lodges part of the transverse sinus. The point of meeting of this angle with the occipital and the mastoid part of the temporal is named the **asterion**.

FIG. 277.—Left parietal bone. Inner surface

Ossification.—The parietal bone is ossified in membrane from a single centre, which appears at the parietal eminence about the eighth week of fetal life. Ossification gradually extends in a radial manner from the centre toward the margins of the bone; the angles are consequently the parts last formed, and it is here that the fontanelles exist. Occasionally the parietal bone is divided into two parts, upper and lower, by an antero-posterior suture.

Articulations.—The parietal articulates with *five* bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

The Frontal Bone (*Os Frontale*).

The **frontal bone** resembles a cockle-shell in form, and consists of two portions—a **vertical** portion, the **squama**, corresponding with the region of the forehead;

and an orbital or horizontal portion, which enters into the formation of the roofs of the orbital and nasal cavities.

Squama (*squama frontalis*).—**Surfaces**.—The **external surface** (Fig. 278) of this portion is convex and usually exhibits, in the lower part of the middle line, the remains of the **frontal or metopic suture**; in infancy this suture divides the bone into two, a condition which may persist throughout life. On either side of this suture, about 3 cm. above the supraorbital margin, is a rounded elevation, the **frontal eminence** (*tuber frontale*). These eminences vary in size in different individuals, are occasionally unsymmetrical, and are especially prominent in young skulls; the surface of the bone above them is smooth, and covered by the galea aponeurotica. Below the frontal eminences, and separated from them by a shallow groove, are two arched elevations, the **superciliary arches**; these are prominent medially, and

FIG. 278 —Frontal bone. Outer surface.

are joined to one another by a smooth elevation named the **glabella**. They are larger in the male than in the female, and their degree of prominence depends to some extent on the size of the frontal air sinuses;¹ prominent ridges are, however, occasionally associated with small air sinuses. Beneath each superciliary arch is a curved and prominent margin, the **supraorbital margin**, which forms the upper boundary of the base of the orbit, and separates the squama from the orbital portion of the bone. The lateral part of this margin is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the medial part is rounded. At the junction of its medial and intermediate thirds is

¹ Some confusion is occasioned to students commencing the study of anatomy by the name "sinus" having been given to two different kinds of space connected with the skull. It may be as well, therefore, to state here that the "sinuses" in the interior of the cranium which produce the grooves on the inner surfaces of the bones are venous channels which convey the blood from the brain, while the "sinuses" external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves, they communicate with the nasal cavities and contain air.

a notch, sometimes converted into a foramen, the **supraorbital notch** or **foramen**, which transmits the supraorbital vessels and nerve. A small aperture in the upper part of the notch transmits a vein from the diploë to join the supraorbital vein. The supraorbital margin ends laterally in the **zygomatic process**, which is strong and prominent, and articulates with the zygomatic bone. Running upward and backward from this process is a well-marked line, the **temporal line**, which divides into the **upper** and **lower temporal lines**, continuous, in the articulated skull, with the corresponding lines on the parietal bone. The area below and behind the temporal line forms the anterior part of the temporal fossa, and gives origin to the Temporalis muscle. Between the supraorbital margins the squama projects downward to a level below that of the zygomatic processes; this portion is known as the **nasal part** and presents a rough, uneven interval, the **nasal notch**, which articulates on either side of the middle line with the nasal bone, and laterally with the frontal process of the maxilla and with the lacrimal. The term **nasion** is applied to the middle of the frontonasal suture. From the centre of the notch the **nasal process** projects downward and forward beneath the nasal bones and frontal processes of the maxillæ, and supports the bridge of the nose. The nasal process ends below in a sharp **spine**, and on either side of this is a small grooved surface which enters into the formation of the roof of the corresponding nasal cavity. The spine forms part of the septum of the nose, articulating in front with the crest of the nasal bones and behind with the perpendicular plate of the ethmoid.

The **internal surface** (Fig. 279) of the squama is concave and presents in the upper part of the middle line a vertical groove, the **sagittal sulcus**, the edges of which unite below to form a ridge, the **frontal crest**; the sulcus lodges the superior sagittal sinus, while its margins and the crest afford attachment to the falx cerebri. The crest ends below in a small notch which is converted into a foramen, the **foramen cecum**, by articulation with the ethmoid. This foramen varies in size in different subjects, and is frequently impervious; when open, it transmits a vein from the nose to the superior sagittal sinus. On either side of the middle line the bone presents depressions for the convolutions of the brain, and numerous small furrows for the anterior branches of the middle meningeal vessels. Several small, irregular fossæ may also be seen on either side of the sagittal sulcus, for the reception of the arachnoid granulations.

Orbital or Horizontal Part (*pars orbitalis*).—This portion consists of two thin triangular plates, the **orbital plates**, which form the vaults of the orbits, and are separated from one another by a median gap, the **ethmoidal notch**.

Surfaces.—The **inferior surface** (Fig. 279) of each orbital plate is smooth and concave, and presents, laterally, under cover of the zygomatic process, a shallow depression, the **lacrimal fossa**, for the lacrimal gland; near the nasal part is a depression, the **fovea trochlearis**, or occasionally a small **trochlear spine**, for the attachment of the cartilaginous pulley of the Obliquus oculi superior. The **superior surface** is **convex**, and marked by depressions for the convolutions of the frontal lobes of the brain, and faint grooves for the meningeal branches of the ethmoidal vessels.

The **ethmoidal notch** separates the two orbital plates; it is quadrilateral, and filled, in the articulated skull, by the cribriform plate of the ethmoid. The margins of the notch present several half-cells which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the ethmoidal air cells. Two **grooves** cross these edges transversely; they are converted into the **anterior** and **posterior ethmoidal canals** by the ethmoid, and open on the medial wall of the orbit. The anterior canal transmits the nasociliary nerve and anterior ethmoidal vessels, the posterior, the posterior ethmoidal nerve and vessels. In front of the ethmoidal notch, on either side of the frontal spine, are the openings of the **frontal air sinuses**. These are two irregular cavities, which extend backward, upward,

and lateralward for a variable distance between the two tables of the skull; they are separated from one another by a thin bony septum, which often deviates to one or other side, with the result that the sinuses are rarely symmetrical. Absent at birth, they are usually fairly well-developed between the seventh and eighth years, but only reach their full size after puberty. They vary in size in different persons, and are larger in men than in women.¹ They are lined by mucous membrane, and each communicates with the corresponding nasal cavity by means of a passage called the **frontonasal duct**.

Articulates

FIG. 279.—Frontal bone. Inner surface.

Borders.—The border of the squama is thick, strongly serrated, bevelled at the expense of the inner table above, where it rests upon the parietal bones, and at the expense of the outer table on either side, where it receives the lateral pressure of those bones; this border is continued below into a triangular, rough surface, which articulates with the great wing of the sphenoid. The posterior borders of the orbital plates are thin and serrated, and articulate with the small wings of the sphenoid.

Structure.—The squama and the zygomatic processes are very thick, consisting of diploic tissue contained between two compact laminae; the diploic tissue is absent in the regions occupied by the frontal air sinuses. The orbital portion is thin, translucent, and composed entirely of compact bone; hence the facility with which instruments can penetrate the cranium through this part of the orbit; when the frontal sinuses are exceptionally large they may extend backward for a considerable distance into the orbital portion, which in such cases also consists of only two tables.

¹ Aldren Turner (*The Accessory Sinuses of the Nose*, 1901) gives the following measurements for a sinus of average size: height, $1\frac{1}{4}$ inches, breadth, 1 inch; depth from before backward, 1 inch.

Ossification (Fig. 280).—The frontal bone is ossified in membrane from *two primary* centres, one for each half, which appear toward the end of the second month of fetal life, one above each supraorbital margin. From each of these centres ossification extends upward to form the corresponding half of the squama, and backward to form the orbital plate. The spine is ossified from a pair of *secondary* centres, on either side of the middle line; similar centres appear in the nasal part and zygomatic processes. At birth the bone consists of two pieces, separated by the frontal suture, which is usually obliterated, except at its lower part, by the eighth year, but occasionally persists throughout life. It is generally maintained that the development of the frontal sinuses begins at the end of the first or beginning of the second year, but Onodi's recent researches indicate that development begins at birth. The sinuses are of considerable size by the seventh or eighth year, but do not attain their full proportions until after puberty.

Articulations.—The frontal articulates with *twelve* bones: the sphenoid, the ethmoid, the two parietals, the two nasals, the two maxillæ, the two lacrimals, and the two zygomatics.

Squama

zomatic process

Spine

FIG. 280.—Frontal bone at birth.

The Temporal Bone (Os Temporale).

The **temporal bones** are situated at the sides and base of the skull. Each consists of five parts, viz., the **squama**, the **petrous**, **mastoid**, and **tympanic parts**, and the **styloid process**.

The Squama (*squama temporalis*).—The squama forms the anterior and upper part of the bone, and is scale-like, thin, and translucent.

Surfaces.—Its **outer surface** (Fig. 281) is smooth and convex; it affords attachment to the Temporalis muscle, and forms part of the temporal fossa; on its hinder part is a vertical groove for the middle temporal artery. A curved line, the **temporal line**, or **supramastoid crest**, runs backward and upward across its posterior part; it serves for the attachment of the temporal fascia, and limits the origin of the Temporalis muscle. The boundary between the squama and the mastoid portion of the bone, as indicated by traces of the original suture, lies about 1 cm. below this line. Projecting from the lower part of the squama is a long, arched process, the **zygomatic process**. This process is at first directed lateralward, its two surfaces looking upward and downward; it then appears as if twisted inward upon itself, and runs forward, its surfaces now looking medialward and lateralward. The superior border is long, thin, and sharp, and serves for the attachment of the temporal fascia; the inferior, short, thick, and arched, has attached to it some fibres of the Masseter. The lateral surface is convex and subcutaneous; the medial is concave, and affords attachment to the Masseter. The anterior end is deeply serrated and articulates with the zygomatic bone. The posterior end is connected to the squama by two roots, the **anterior** and **posterior roots**. The posterior root, a prolongation of the upper border, is strongly marked; it runs backward above the external acoustic meatus, and is continuous with the temporal line. The anterior root, continuous with the lower border, is short but broad and strong; it is directed medialward and ends in a rounded eminence, the **articular tubercle** (*eminentia articularis*). This tubercle forms the front boundary of the mandibular fossa, and in the recent state is covered with cartilage. In front of the articular tubercle is a small triangular area which assists in forming the infratemporal fossa; this area is separated from the outer surface of the squama by a ridge which is continuous behind with the anterior root of the zygomatic process, and in front, in the

articulated skull, with the infratemporal crest on the great wing of the sphenoid. Between the posterior wall of the external acoustic meatus and the posterior root of the zygomatic process is the area called the **suprameatal triangle** (Macewen), or **mastoid fossa**, through which an instrument may be pushed into the tympanic antrum. At the junction of the anterior root with the zygomatic process is a projection for the attachment of the temporomandibular ligament; and behind the anterior root is an oval depression, forming part of the mandibular fossa, for the reception of the condyle of the mandible. The **mandibular fossa** (*glenoid fossa*) is bounded, in front, by the articular tubercle; behind, by the tympanic part of the bone, which separates it from the external acoustic meatus; it is divided into two parts by a narrow slit, the **petrotympanic fissure** (*Glaserian fissure*). The

middle
artery

FIG. 281 —Left temporal bone. Outer surface.

anterior part, formed by the squama, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the mandible. Behind this part of the fossa is a small conical eminence; this is the representative of a prominent tubercle which, in some mammals, descends behind the condyle of the mandible, and prevents its backward displacement. The posterior part of the mandibular fossa, formed by the tympanic part of the bone, is non-articular, and sometimes lodges a portion of the parotid gland. The petrotympanic fissure leads into the middle ear or tympanic cavity; it lodges the anterior process of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a canal (*canal of Huguier*), separated from the anterior edge of the petrotympanic fissure by a thin scale of bone and situated on the lateral side of the auditory tube, in the retiring angle between the squama and the petrous portion of the temporal.

The **internal surface** of the squama (Fig. 282) is concave; it presents depressions corresponding to the convolutions of the temporal lobe of the brain, and grooves for the branches of the middle meningeal vessels.

Borders.—The **superior border** is thin, and bevelled at the expense of the internal table, so as to overlap the squamous border of the parietal bone, forming with it the squamosal suture. Posteriorly, the superior border forms an angle, the **parietal notch**, with the mastoid portion of the bone. The **antero-inferior border** is thick, serrated, and bevelled at the expense of the inner table above and of the outer below, for articulation with the great wing of the sphenoid.

Mastoid Portion (*pars mastoidea*).—The mastoid portion forms the posterior part of the bone.

Aquæductus cochleæ
Internal acoustic meatus

FIG. 282.—Left temporal bone. Inner surface.

Surfaces.—Its **outer surface** (Fig. 281) is rough, and gives attachment to the Occipitalis and Auricularis posterior. It is perforated by numerous foramina; one of these, of large size, situated near the posterior border, is termed the **mastoid foramen**; it transmits a vein to the transverse sinus and a small branch of the occipital artery to the dura mater. The position and size of this foramen are very variable; it is not always present; sometimes it is situated in the occipital bone, or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the **mastoid process**, the size and form of which vary somewhat; it is larger in the male than in the female. This process serves for the attachment of the Sternocleidomastoideus, Splenius capitis, and Longissimus capitis. On the medial side of the process is a deep groove, the **mastoid notch** (*digastric fossa*), for the attachment of the Digastricus; medial to this is a shallow furrow, the **occipital groove**, which lodges the occipital artery.

The inner surface of the mastoid portion presents a deep, curved groove, the **sigmoid sulcus**, which lodges part of the transverse sinus; in it may be seen the opening of the mastoid foramen. The groove for the transverse sinus is separated from the innermost of the mastoid air cells by a very thin lamina of bone, and even this may be partly deficient.

Borders.—The superior border of the mastoid portion is broad and serrated, for articulation with the mastoid angle of the parietal. The posterior border, also serrated, articulates with the inferior border of the occipital between the lateral angle and jugular process. Anteriorly the mastoid portion is fused with the descending process of the squama above; below it enters into the formation of the external acoustic meatus and the tympanic cavity.

ani

nal

FIG. 283.—Coronal section of right temporal bone.

A section of the mastoid process (Fig. 283) shows it to be hollowed out into a number of spaces, the **mastoid cells**, which exhibit the greatest possible variety as to their size and number. At the upper and front part of the process they are large and irregular and contain air, but toward the lower part they diminish in size, while those at the apex of the process are frequently quite small and contain marrow; occasionally they are entirely absent, and the mastoid is then solid throughout. In addition to these a large irregular cavity is situated at the upper and front part of the bone. It is called the **tympanic antrum**, and must be distinguished from the mastoid cells, though it communicates with them. Like the mastoid cells it is filled with air and lined by a prolongation of the mucous membrane of the tympanic cavity, with which it communicates. The tympanic antrum is bounded above by a thin plate of bone, the **tegmen tympani**, which separates it from the middle fossa of the base of the skull; below by the mastoid process; laterally by the squama just below the temporal line, and medially by the lateral semicircular canal of the internal ear which projects into its cavity. It opens in front into that portion of the tympanic cavity which is known as the **attic** or **epitympanic**

recess. The tympanic antrum is a cavity of some considerable size at the time of birth; the mastoid air cells may be regarded as diverticula from the antrum, and begin to appear at or before birth; by the fifth year they are well-marked, but their development is not completed until toward puberty.

Petrous Portion (*pars petrosa* [*pyramis*]).—The petrous portion or pyramid is pyramidal and is wedged in at the base of the skull between the sphenoid and occipital. Directed medialward, forward, and a little upward, it presents for examination a base, an apex, three surfaces, and three angles, and contains, in its interior, the essential parts of the organ of hearing.

Base.—The base is fused with the internal surfaces of the squama and mastoid portion.

Apex.—The apex, rough and uneven, is received into the angular interval between the posterior border of the great wing of the sphenoid and the basilar part of the occipital; it presents the anterior or internal orifice of the carotid canal, and forms the postero-lateral boundary of the foramen lacrum.

Surfaces.—The anterior surface forms the posterior part of the middle fossa of the base of the skull, and is continuous with the inner surface of the squamous portion, to which it is united by the petrosquamous suture, remains of which are distinct even at a late period of life. It is marked by depressions for the convolutions of the brain, and presents six points for examination: (1) near the centre, an eminence (*eminencia arcuata*) which indicates the situation of the superior semicircular canal; (2) in front of and a little lateral to this eminence, a depression indicating the position of the tympanic cavity: here the layer of bone which separates the tympanic from the cranial cavity is extremely thin, and is known as the *tegumen tympani*; (3) a shallow groove, sometimes double, leading lateralward and backward to an oblique opening, the hiatus of the facial canal, for the passage of the greater superficial petrosal nerve and the petrosal branch of the middle meningeal artery; (4) lateral to the hiatus, a smaller opening, occasionally seen, for the passage of the lesser superficial petrosal nerve; (5) near the apex of the bone, the termination of the carotid canal, the wall of which in this situation is deficient in front; (6) above this canal the shallow trigeminal impression for the reception of the semilunar ganglion.

The posterior surface (Fig. 282) forms the front part of the posterior fossa of the base of the skull, and is continuous with the inner surface of the mastoid portion. Near the centre is a large orifice, the internal acoustic meatus, the size of which varies considerably; its margins are smooth and rounded, and it leads into a short canal, about 1 cm. in length, which runs lateralward. It transmits the facial and acoustic nerves and the internal auditory branch of the basilar artery. The lateral end of the canal is closed by a vertical plate, which is divided by a horizontal crest, the *crista falciformis*, into two unequal portions (Fig. 284). Each portion is further subdivided by a vertical ridge into an anterior and a posterior part. In the portion beneath the crista falciformis are three sets of foramina; one group, just below the posterior part of the crest, situated in the *area cribrosa media*, consists of several small openings for the nerves to the sacculæ; below and

Fig. 284

Fig. 284.—Diagrammatic view of the fundus of the right internal acoustic meatus. (Testut.) 1. Crista falciformis. 2. Area facialis, with (2') internal opening of the facial canal. 3. Ridge separating the area facialis from the area cribrosa superior. 4. Area cribrosa superior, with (4') openings for nerve filaments. 5. Anterior inferior cribriform area, with (5') the tractus spiralis foraminosus, and (5'') the canalis centralis of the cochlea. 6. behind this area is the **foramen singulare**, or opening for the nerve to the posterior semicircular duct; in front of and below the first is the **tractus spiralis foraminosus**, consisting of a number of small spirally arranged openings, which encircle the **canalis centralis cochleæ**; these openings together with this central canal transmit the nerves to the cochlea. The portion above the **crista falciformis** presents behind, the **area cribrosa superior**, pierced by a series of small openings, for the passage of the nerves to the utricle and the superior and lateral semicircular ducts, and, in front, the **area facialis**, with one large opening, the commencement of the canal for the facial nerve (**aquæductus Fallopii**). Behind the internal acoustic meatus is a small slit almost hidden by a thin plate of bone, leading to a canal, the **aquæductus vestibuli**, which transmits the ductus endolymphaticus together with a small artery and vein. Above and between these two openings is an irregular depression which lodges a process of the dura mater and transmits a small vein; in the infant this depression is represented by a large fossa, the **subarcuate fossa**, which extends backward as a blind tunnel under the superior semicircular canal.

FIG. 285.—Left temporal bone. Inferior surface.

The **inferior surface** (Fig. 285) is rough and irregular, and forms part of the exterior of the base of the skull. It presents eleven points for examination: (1) near the apex is a rough surface, quadrilateral in form, which serves partly for the attachment of the Levator veli palatini and the cartilaginous portion of the auditory tube, and partly for connection with the basilar part of the occipital bone through the intervention of some dense fibrous tissue; (2) behind this is the large circular aperture of the **carotid canal**, which ascends at first vertically, and then, making a bend, runs horizontally forward and medialward; it transmits into the cranium the internal carotid artery, and the carotid plexus of nerves; (3) medial to the opening for the carotid canal and close to its posterior border, in front of

the jugular fossa, is a triangular depression; at the apex of this is a small opening, the *aquaeductus cochleae*, which lodges a tubular prolongation of the dura mater and transmits a vein from the cochlea to join the internal jugular; (4) behind these openings is a deep depression, the *jugular fossa*, of variable depth and size in different skulls; it lodges the bulb of the internal jugular vein; (5) in the bony ridge dividing the carotid canal from the jugular fossa is the small *inferior tympanic canaliculus* for the passage of the tympanic branch of the glossopharyngeal nerve; (6) in the lateral part of the jugular fossa is the *mastoid canaliculus* for the entrance of the auricular branch of the vagus nerve; (7) behind the jugular fossa is a quadrilateral area, the *jugular surface*, covered with cartilage in the recent state, and articulating with the jugular process of the occipital bone; (8) extending backward from the carotid canal is the *vaginal process*, a sheath-like plate of bone, which divides behind into two laminae; the lateral lamina is continuous with the tympanic part of the bone, the medial with the lateral margin of the jugular surface; (9) between these laminae is the *styloid process*, a sharp spine, about 2.5 cm. in length; (10) between the styloid and mastoid processes is the *stylomastoid foramen*; it is the termination of the facial canal, and transmits the facial nerve and stylomastoid artery; (11) situated between the tympanic portion and the mastoid process is the *tympanomastoid fissure*, for the exit of the auricular branch of the vagus nerve.

Angles.—The *superior angle*, the longest, is grooved for the superior petrosal sinus, and gives attachment to the tentorium cerebelli; at its medial extremity is a notch, in which the trigeminal nerve lies. The *posterior angle* is intermediate in length between the superior and the anterior. Its medial half is marked by a sulcus, which forms, with a corresponding sulcus on the occipital bone, the channel for the inferior petrosal sinus. Its lateral half presents an excavation—the *jugular fossa*—which, with the jugular notch on the occipital, forms the *jugular foramen*; an eminence occasionally projects from the centre of the fossa, and divides the foramen into two. The *anterior angle* is divided into two parts—a lateral joined to the squama by a suture (*petrosquamous*), the remains of which are more or less distinct; a medial, free, which articulates with the spinous process of the sphenoid.

At the angle of junction of the petrous part and the squama are two canals, one above the other, and separated by a thin plate of bone, the *septum canalis musculotubarii* (*processus cochleariformis*); both canals lead into the tympanic cavity. The upper one (*semicanalis m. tensoris tympani*) transmits the Tensor tympani, the lower one (*semicanalis tubae auditivae*) forms the bony part of the auditory tube.

The tympanic cavity, auditory ossicles, and internal ear, are described with the organ of hearing.

Tympanic Part (*pars tympanica*).—The tympanic part is a curved plate of bone lying below the squama and in front of the mastoid process.

Surfaces.—Its *postero-superior surface* is concave, and forms the anterior wall, the floor, and part of the posterior wall of the bony external acoustic meatus. Medially, it presents a narrow furrow, the *tympanic sulcus*, for the attachment of the tympanic membrane. Its *antero-inferior surface* is quadrilateral and slightly concave; it constitutes the posterior boundary of the mandibular fossa, and is in contact with the retromandibular part of the parotid gland.

Borders.—Its *lateral border* is free and rough, and gives attachment to the cartilaginous part of the external acoustic meatus. Internally, the tympanic part is fused with the petrous portion, and appears in the retreating angle between it and the squama, where it lies below and lateral to the orifice of the auditory tube. Posteriorly, it blends with the squama and mastoid part, and forms the anterior boundary of the tympanomastoid fissure. Its *upper border* fuses laterally with the back of the postglenoid process, while medially it bounds the petro-

tympanic fissure. The medial part of the lower border is thin and sharp; its lateral part splits to enclose the root of the styloid process, and is therefore named the **vaginal process**. The central portion of the tympanic part is thin, and in a considerable percentage of skulls is perforated by a hole, the **foramen of Huschke**.

The **external acoustic meatus** is nearly 2 cm. long and is directed inward and slightly forward: at the same time it forms a slight curve, so that the floor of the canal is convex upward. In sagittal section it presents an oval or elliptical shape with the long axis directed downward and slightly backward. Its anterior wall and floor and the lower part of its posterior wall are formed by the tympanic part; the roof and upper part of the posterior wall by the squama. Its inner end is closed, in the recent state, by the tympanic membrane; the upper limit of its outer orifice is formed by the posterior root of the zygomatic process, immediately below which there is sometimes seen a small spine, the **suprameatal spine**, situated at the upper and posterior part of the orifice.

Styloid Process (*processus styloideus*).—The styloid process is slender, pointed, and of varying length; it projects downward and forward, from the under surface of the temporal bone. Its proximal part (*tympanohyal*) is ensheathed by the vaginal process of the tympanic portion, while its distal part (*stylohyal*) gives attachment to the stylohyoid and stylomandibular ligaments, and to the Styloglossus, Stylohyoideus, and Stylopharyngeus muscles. The stylohyoid ligament extends from the apex of the process to the lesser cornu of the hyoid bone, and in some instances is partially, in others completely, ossified.

FIG. 286.—The three principal parts of the temporal bone at birth. 1. Outer surface of petromastoid part. 2. Outer surface of tympanic ring. 3. Inner surface of squama.

Structure.—The structure of the squama is like that of the other cranial bones: the mastoid portion is spongy, and the petrous portion dense and hard.

Ossification.—The temporal bone is ossified from *eight* centres, exclusive of those for the internal ear and the tympanic ossicles, viz., one for the squama including the zygomatic process, one for the tympanic part, four for the petrous and mastoid parts, and two for the styloid process. Just before the close of fetal life (Fig. 286) the temporal bone consists of three principal parts: 1. The *squama* is ossified in membrane from a single nucleus, which appears near the root of the zygomatic process about the second month. 2. The *petromastoid* part is developed from four centres, which make their appearance in the cartilaginous ear capsule about the fifth or sixth month. One (*prootic*) appears in the neighborhood of the eminentia arcuata, spreads in front and above the internal acoustic meatus and extends to the apex of the bone; it forms part of the cochlea, vestibule, superior semicircular canal, and medial wall of the tympanic cavity. A second (*opisthotic*) appears at the promontory on the medial wall of the tympanic cavity and surrounds the fenestra cochleae; it forms the floor of the tympanic cavity and vestibule, surrounds the carotid canal, invests the lateral and lower part of the cochlea, and spreads medially below the internal

acoustic meatus. A third (*pteryotic*) roofs in the tympanic cavity and antrum; while the fourth (*epiotic*) appears near the posterior semicircular canal and extends to form the mastoid process (Vrolik). 3. The *tympanic ring* is an incomplete circle, in the concavity of which is a groove, the tympanic sulcus, for the attachment of the circumference of the tympanic membrane. This ring expands to form the tympanic part, and is ossified in membrane from a single centre which appears about the third month. The *styloid process* is developed from the proximal part of the cartilage of the second branchial or hyoid arch by two centres: one for the proximal part, the *tympanohyal*, appears before birth; the other, comprising the rest of the process, is named the *stylohyal*, and does not appear until after birth. The tympanic ring unites with the squama shortly before birth; the petromastoid part and squama join during the first year, and the tympanohyal portion of the styloid process about the same time (Figs. 287, 288). The stylohyal does not unite with the rest of the bone until after puberty, and in some skulls never at all.

FIG. 287.—Temporal bone at birth. Outer aspect.

FIG. 288.—Temporal bone at birth. Inner aspect.

The chief subsequent changes in the temporal bone apart from increase in size are: (1) The tympanic ring extends outward and backward to form the tympanic part. This extension does not, however, take place at an equal rate all around the circumference of the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the *foramen of Huschke*; this foramen is usually closed about the fifth year, but may persist throughout life. (2) The mandibular fossa is at first extremely shallow, and looks lateralward as well as downward; it becomes deeper and is ultimately directed downward. Its change in direction is accounted for as follows. The part of the squama which forms the fossa lies at first below the level of the zygomatic process. As, however, the base of the skull increases in width, this lower part of the squama is directed horizontally inward to contribute to the middle fossa of the skull, and its surfaces therefore come to look upward and downward; the attached portion of the zygomatic process also becomes everted, and projects like a shelf at right angles to the squama. (3) The mastoid portion is at first quite flat, and the stylo-mastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the air cells the outer part of the mastoid portion grows downward and forward to form the mastoid process, and the styloid process and stylo-mastoid foramen now come to lie on the under surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the facial canal. (4) The downward and forward growth of the mastoid process also pushes forward the tympanic part, so that the portion of it which formed the original floor of the meatus and contained the foramen of Huschke is ultimately found in the anterior wall. (5) The fossa subarcuata becomes filled up and almost obliterated.

Articulations.—The temporal articulates with *five* bones: occipital, parietal, sphenoid, mandible, and zygomatic.

The Sphenoidal Bone (Os Sphenoidal; Sphenoid Bone).

The **sphenoidal bone** is situated at the base of the skull in front of the temporals and basilar part of the occipital. It somewhat resembles a bat with its wings

extended, and is divided into a median portion or body, two great and two small wings extending outward from the sides of the body, and two pterygoid processes which project from it below.

Body (*corpus sphenoidalis*).—The body, more or less cubical in shape, is hollowed out in its interior to form two large cavities, the **sphenoidal air sinuses**, which are separated from each other by a septum.

Surfaces.—The **superior surface** of the body (Fig. 289) presents in front a prominent spine, the **ethmoidal spine**, for articulation with the cribriform plate of the ethmoid; behind this is a smooth surface slightly raised in the middle line, and grooved on either side for the olfactory lobes of the brain. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the **chiasmatic groove** (*optic groove*), above and behind which lies the optic chiasma; the groove ends on either side in the **optic foramen**, which transmits the optic nerve and ophthalmic artery into the orbital cavity. Behind the chiasmatic groove is an olive-like elevation, the **tuberculum sellae**; and still more posteriorly, a deep depression, the **sella turcica**, the deepest part of which lodges the hypophysis

FIG. 289.—Sphenoidal bone. Upper surface

cerebri and is known as the **fossa hypophyseos**. The anterior boundary of the sella turcica is completed by two small eminences, one on either side, called the **middle clinoid processes**, while the posterior boundary is formed by a square-shaped plate of bone, the **dorsum sellae**, ending at its superior angles in two tubercles, the **posterior clinoid processes**, the size and form of which vary considerably in different individuals. The posterior clinoid processes deepen the sella turcica, and give attachment to the tentorium cerebelli. On either side of the dorsum sellae is a notch for the passage of the abducent nerve, and below the notch a sharp process, the **petrosal process**, which articulates with the apex of the petrous portion of the temporal bone, and forms the medial boundary of the foramen lacerum. Behind the dorsum sellae is a shallow depression, the **clivus**, which slopes obliquely backward, and is continuous with the groove on the basilar portion of the occipital bone; it supports the upper part of the pons.

The **lateral surfaces** of the body are united with the great wings and the medial pterygoid plates. Above the attachment of each great wing is a broad groove, curved something like the italic letter *f*; it lodges the internal carotid artery and

the cavernous sinus, and is named the **carotid groove**. Along the posterior part of the lateral margin of this groove, in the angle between the body and great wing, is a ridge of bone, called the **lingula**.

The **posterior surface**, quadrilateral in form (Fig. 291), is joined, during infancy and adolescence, to the basilar part of the occipital bone by a plate of cartilage. Between the eighteenth and twenty-fifth years this becomes ossified, ossification commencing above and extending downward.

The **anterior surface** of the body (Fig. 290) presents, in the middle line, a vertical crest, the **sphenoidal crest**, which articulates with the perpendicular plate of the ethmoid, and forms part of the septum of the nose. On either side of the crest is an irregular opening leading into the corresponding **sphenoidal air sinus**. These sinuses are two large, irregular cavities hollowed out of the interior of the body of the bone, and separated from one another by a bony septum, which is commonly bent to one or the other side. They vary considerably in form and size,¹ are seldom symmetrical, and are often partially subdivided by irregular bony laminae.

FIG. 290.—Sphenoidal bone. Anterior and inferior surfaces.

Occasionally, they extend into the basilar part of the occipital nearly as far as the foramen magnum. They begin to be developed before birth, and are of a considerable size by the age of six. They are partially closed, in front and below, by two thin, curved plates of bone, the **sphenoidal conchae** (see page 250), leaving in the articulated skull a round opening at the upper part of each sinus by which it communicates with the upper and back part of the nasal cavity and occasionally with the posterior ethmoidal air cells. The lateral margin of the anterior surface is serrated, and articulates with the lamina papyracea of the ethmoid, completing the posterior ethmoidal cells; the lower margin articulates with the orbital process of the palatine bone, and the upper with the orbital plate of the frontal bone.

The **inferior surface** presents, in the middle line, a triangular spine, the **sphenoidal rostrum**, which is continuous with the sphenoidal crest on the anterior surface, and is received in a deep fissure between the alae of the vomer. On either side of the rostrum is a projecting lamina, the **vaginal process**, directed medialward from the base of the medial pterygoid plate, with which it will be described.

¹ Aldren Turner (*op. cit.*) gives the following as their average measurements: vertical height, $\frac{1}{8}$ inch; antero-posterior depth, $\frac{7}{8}$ inch; transverse breadth, $\frac{3}{4}$ inch.

The Great Wings (*alae magnae*).—The great wings, or **ali-sphenoids**, are two strong processes of bone, which arise from the sides of the body, and are curved upward, lateralward, and backward; the posterior part of each projects as a triangular process which fits into the angle between the squama and the petrous portion of the temporal and presents at its apex a downwardly directed process, the **spina angularis** (*sphenoidal spine*).

Surfaces.—The **superior** or **cerebral surface** of each great wing (Fig. 289) forms part of the middle fossa of the skull; it is deeply concave, and presents depressions for the convolutions of the temporal lobe of the brain. At its anterior and medial part is a circular aperture, the **foramen rotundum**, for the transmission of the maxillary nerve. Behind and lateral to this is the **foramen ovale**, for the transmission of the mandibular nerve, the accessory meningeal artery, and sometimes the lesser superficial petrosal nerve.¹ Medial to the foramen ovale, a small aperture, the **foramen Vesalii**, may occasionally be seen opposite the root of the pterygoid process; it opens below near the scaphoid fossa, and transmits a small vein from the cavernous sinus. Lastly, in the posterior angle, near to and in front of the spine, is a short canal, sometimes double, the **foramen spinosum**, which transmits the middle meningeal vessels and a recurrent branch from the mandibular nerve.

Anterior clinoid process

rotundum

ularis

*late
ale*

Rostrum

FIG. 291.—Sphenoidal bone. Upper and posterior surfaces.

The **lateral surface** (Fig. 290) is convex, and divided by a transverse ridge, the **infratemporal crest**, into two portions. The superior or temporal portion, convex from above downward, concave from before backward, forms a part of the temporal fossa, and gives attachment to the Temporalis; the inferior or infratemporal, smaller in size and concave, enters into the formation of the infratemporal fossa, and, together with the infratemporal crest, affords attachment to the Pterygoideus externus. It is pierced by the foramen ovale and foramen spinosum, and at its posterior part is the spina angularis, which is frequently grooved on its medial surface for the chorda tympani nerve. To the spina angularis are attached the sphenomandibular ligament and the Tensor veli palatini. Medial to the anterior extremity of the infratemporal crest is a triangular process which serves to increase

¹ The lesser superficial petrosal nerve sometimes passes through a special canal (*canaliculus innominatus* of Arnold) situated medial to the foramen spinosum.

the attachment of the Pterygoideus externus; extending downward and medialward from this process on to the front part of the lateral pterygoid plate is a ridge which forms the anterior limit of the infratemporal surface, and, in the articulated skull, the posterior boundary of the pterygomaxillary fissure.

The **orbital surface** of the great wing (Fig. 290), smooth, and quadrilateral in shape, is directed forward and medialward and forms the posterior part of the lateral wall of the orbit. Its upper serrated edge articulates with the orbital plate of the frontal. Its inferior rounded border forms the postero-lateral boundary of the inferior orbital fissure. Its medial sharp margin forms the lower boundary of the superior orbital fissure and has projecting from about its centre a little tubercle which gives attachment to the inferior head of the Rectus lateralis oculi; at the upper part of this margin is a notch for the transmission of a recurrent branch of the lacrimal artery. Its lateral margin is serrated and articulates with the zygomatic bone. Below the medial end of the superior orbital fissure is a grooved surface, which forms the posterior wall of the pterygopalatine fossa, and is pierced by the foramen rotundum.

Margin (Fig. 289).—Commencing from behind, that portion of the circumference of the great wing which extends from the body to the spine is irregular. Its medial half forms the anterior boundary of the foramen lacerum, and presents the posterior aperture of the pterygoid canal for the passage of the corresponding nerve and artery. Its lateral half articulates, by means of a synchondrosis, with the petrous portion of the temporal, and between the two bones on the under surface of the skull, is a furrow, the *sulcus tubae*, for the lodgement of the cartilaginous part of the auditory tube. In front of the spine the circumference presents a concave, serrated edge, bevelled at the expense of the inner table below, and of the outer table above, for articulation with the temporal squama. At the tip of the great wing is a triangular portion, bevelled at the expense of the internal surface, for articulation with the sphenoidal angle of the parietal bone; this region is named the **pteron**. Medial to this is a triangular, serrated surface, for articulation with the frontal bone; this surface is continuous medially with the sharp edge, which forms the lower boundary of the superior orbital fissure, and laterally with the serrated margin for articulation with the zygomatic bone.

The Small Wings (*alae parvae*).—The small wings or **orbito-sphenoids** are two thin triangular plates, which arise from the upper and anterior parts of the body, and, projecting lateralward, end in sharp points (Fig. 289).

Surfaces.—The **superior surface** of each is flat, and supports part of the frontal lobe of the brain. The **inferior surface** forms the back part of the roof of the orbit, and the upper boundary of the **superior orbital fissure**. This fissure is of a triangular form, and leads from the cavity of the cranium into that of the orbit: it is bounded *medially* by the body; *above*, by the small wing; *below*, by the medial margin of the orbital surface of the great wing; and is completed *laterally* by the frontal bone. It transmits the oculomotor, trochlear, and abducent nerves, the three branches of the ophthalmic division of the trigeminal nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery to the dura mater, and the ophthalmic vein.

Borders.—The **anterior border** is serrated for articulation with the frontal bone. The **posterior border**, smooth and rounded, is received into the lateral fissure of the brain; the medial end of this border forms the **anterior clinoid process**, which gives attachment to the tentorium cerebelli; it is sometimes joined to the middle clinoid process by a spicule of bone, and when this occurs the termination of the groove for the internal carotid artery is converted into a foramen (*carotico-clinoid*). The small wing is connected to the body by two roots, the upper thin and flat,

the lower thick and triangular; between the two roots is the **optic foramen**, for the transmission of the optic nerve and ophthalmic artery.

Pterygoid Processes (*processus pterygoidei*).—The pterygoid processes, one on either side, descend perpendicularly from the regions where the body and great wings unite. Each process consists of a medial and a lateral plate, the upper parts of which are fused anteriorly; a vertical sulcus, the **pterygopalatine groove**, descends on the front of the line of fusion. The plates are separated below by an angular cleft, the **pterygoid fissure**, the margins of which are rough for articulation with the pyramidal process of the palatine bone. The two plates diverge behind and enclose between them a V-shaped fossa, the **pterygoid fossa**, which contains the Pterygoideus internus and Tensor veli palatini. Above this fossa is a small, oval, shallow depression, the **scaphoid fossa**, which gives origin to the Tensor veli palatini. The anterior surface of the pterygoid process is broad and triangular near its root, where it forms the posterior wall of the pterygopalatine fossa and presents the anterior orifice of the pterygoid canal.

Lateral Pterygoid Plate.—The lateral pterygoid plate is broad, thin, and everted; its **lateral surface** forms part of the medial wall of the infratemporal fossa, and gives attachment to the Pterygoideus externus; its **medial surface** forms part of the pterygoid fossa, and gives attachment to the Pterygoideus internus.

Medial Pterygoid Plate.—The medial pterygoid plate is narrower and longer than the lateral; it curves lateralward at its lower extremity into a hook-like process, the **pterygoid hamulus**, around which the tendon of the Tensor veli palatini glides. The **lateral surface** of this plate forms part of the pterygoid fossa, the **medial surface** constitutes the lateral boundary of the choana or posterior aperture of the corresponding nasal cavity. Superiorly the medial plate is prolonged on to the under surface of the body as a thin lamina, named the **vaginal process**, which articulates in front with the sphenoidal process of the palatine and behind this with the ala of the vomer. The angular prominence between the posterior margin of the vaginal process and the medial border of the scaphoid fossa is named the **pterygoid tubercle**, and immediately above this is the posterior opening of the pterygoid canal. On the under surface of the vaginal process is a furrow, which is converted into a canal by the sphenoidal process of the palatine bone, for the transmission of the pharyngeal branch of the internal maxillary artery and the pharyngeal nerve from the sphenopalatine ganglion. The pharyngeal aponeurosis is attached to the entire length of the posterior edge of the medial plate, and the Constrictor pharyngis superior takes origin from its lower third. Projecting backward from near the middle of the posterior edge of this plate is an angular process, the **processus tubarius**, which supports the pharyngeal end of the auditory tube. The anterior margin of the plate articulates with the posterior border of the vertical part of the palatine bone.

The Sphenoidal Conchæ (*conchæ sphenoidales; sphenoidal turbinated processes*).—The sphenoidal conchæ are two thin, curved plates, situated at the anterior and lower part of the body of the sphenoid. An aperture of variable size exists in the anterior wall of each, and through this the sphenoidal sinus opens into the nasal cavity. Each is irregular in form, and tapers to a point behind, being broader and thinner in front. Its upper surface is concave, and looks toward the cavity of the sinus; its under surface is convex, and forms part of the roof of the corresponding nasal cavity. Each bone articulates in front with the ethmoid, laterally with the palatine; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process laterally and the rostrum of the sphenoid medially. A small portion of the sphenoidal concha sometimes enters into the formation of the medial wall of the orbit, between the lamina papyracea of the ethmoid in front, the orbital plate of the palatine below, and the frontal bone above.

Ossification.—Until the seventh or eighth month of fetal life the body of the sphenoid consists of two parts, viz., one in front of the tuberculum sellae, the *presphenoid*, with which the small wings are continuous; the other, comprising the sella turcica and dorsum sellae, the *postsphenoid*, with which are associated the great wings, and pterygoid processes. The greater part of the bone is ossified in cartilage. There are fourteen centres in all, six for the presphenoid and eight for the postsphenoid.

Presphenoid.—About the ninth week of fetal life an ossific centre appears for each of the small wings (orbitosphenoids) just lateral to the optic foramen; shortly afterward two nuclei appear in the presphenoid part of the body. The sphenoidal conchæ are each developed from a centre which makes its appearance about the fifth month;¹ at birth they consist of small triangular laminae, and it is not until the third year that they become hollowed out and cone-shaped; about the fourth year they fuse with the labyrinths of the ethmoid, and between the ninth and twelfth years they unite with the sphenoid.

Postsphenoid.—The first ossific nuclei are those for the great wings (ali-sphenoids). One makes its appearance in each wing between the foramen rotundum and foramen ovale about the eighth week. The orbital plate and that part of the sphenoid which is found in the temporal fossa, as well as the lateral pterygoid plate, are ossified in membrane (Fawcett²). Soon after, the centres for the postsphenoid part of the body appear, one on either side of the sella turcica, and become blended together about the middle of fetal life. Each medial pterygoid plate (with the exception of its hamulus) is ossified in membrane, and its centre probably appears about the ninth or tenth week; the hamulus becomes chondrified during the third month, and almost at once undergoes ossification (Fawcett³). The medial joins the lateral pterygoid plate about the sixth month. About the fourth month a centre appears for each lingula and speedily joins the rest of the bone.

The presphenoid is united to the postsphenoid about the eighth month, and at birth the bone is in three pieces (Fig. 292): a central, consisting of the body and small wings, and two lateral, each comprising a great wing and pterygoid process. In the first year after birth the great wings and body unite, and the small wings extend inward above the anterior part of the body, and, meeting with each other in the middle line, form an elevated smooth surface, termed the *jugum sphenoidale*. By the twenty-fifth year the sphenoid and occipital are completely fused. Between the pre- and postsphenoid there are occasionally seen the remains of a canal, the *canalis craniopharyngeus*, through which, in early fetal life, the hypophyseal diverticulum of the buccal ectoderm is transmitted (see page 166).

FIG. 292.—Sphenoidal bone at birth. Posterior aspect.

The sphenoidal sinuses are present as minute cavities at the time of birth (Onodi), but do not attain their full size until after puberty.

Certain intrinsic ligaments are attached to the sphenoid. The more important of these are: the *pterygo-sphenous*, stretching between the spina angularis and the lateral pterygoid plate (see *cervical fascia*); the *interclinoid*, a fibrous process joining the anterior to the posterior clinoid process; and the *caroticoclinoid*, connecting the anterior to the middle clinoid process. These ligaments occasionally ossify.

Articulations.—The sphenoid articulates with *twelve* bones: four single, the vomer, ethmoid, frontal, and occipital; and four paired, the parietal, temporal, zygomatic, and palatine.⁴

The Ethmoidal Bone (Os Ethmoidale; Ethmoid Bone).

The **ethmoidal bone** is exceedingly light and spongy, and cubical in shape; it is situated at the anterior part of the base of the cranium, between the two orbits, at the roof of the nose, and contributes to each of these cavities. It consists of four parts: a **horizontal or cribriform plate**, forming part of the base of the cranium; a **perpendicular plate**, constituting part of the nasal septum; and two **lateral masses or labyrinths**.

¹ According to Cleland, each sphenoidal concha is ossified from four centres.

² Journal of Anatomy and Physiology, 1910, vol. xiv.

³ Anatomischer Anzeiger, March, 1905.

⁴ It also sometimes articulates with the tuberosity of the maxilla (see page 257).

Cribiform Plate (*lamina cribrosa; horizontal lamina*).—The cribriform plate (Fig. 293) is received into the ethmoidal notch of the frontal bone and roofs in the nasal cavities. Projecting upward from the middle line of this plate is a thick, smooth, triangular process, the *crista galli*, so called from its resemblance to a cock's comb. Its posterior border, long, thin, and slightly curved, serves for the attachment of the *falx cerebri*.

Perpendicular plate

plate

ethmoidal

ethmoidal

Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting *ala*, which are received into corresponding depressions in the frontal bone and complete the *foramen cecum*. Its sides are smooth, and sometimes bulging from the presence of a small air sinus in the interior. On either side of the *crista galli*, the cribriform plate is narrow and deeply grooved; it supports the olfactory bulb and is perforated by foramina for the passage of the olfactory nerves. The foramina in the middle of the groove are small and transmit the nerves to the

FIG. 293.—Ethmoidal bone from above.

roof of the nasal cavity; those at the medial and lateral parts of the groove are larger—the former transmit the nerves to the upper part of the nasal septum, the latter those to the superior nasal concha. At the front part of the cribriform plate, on either side of the *crista galli*, is a small fissure which is occupied by a process of *dura mater*. Lateral to this fissure is a notch or foramen which transmits the *nasociliary nerve*; from this notch a groove extends backward to the anterior ethmoidal foramen.

with

with

FIG. 294.—Perpendicular plate of ethmoid. Shown by removing the right labyrinth.

Perpendicular Plate (*lamina perpendicularis; vertical plate*).—The perpendicular plate (Figs. 294, 295) is a thin, flattened lamina, polygonal in form, which descends from the under surface of the cribriform plate, and assists in forming the septum of the nose; it is generally deflected a little to one or other side. The *anterior border*

articulates with the spine of the frontal bone and the crest of the nasal bones. The **posterior border** articulates by its upper half with the sphenoidal crest, by its lower with the vomer. The **inferior border** is thicker than the posterior, and serves for the attachment of the septal cartilage of the nose. The surfaces of the plate are smooth, except above, where numerous grooves and canals are seen; these lead from the medial foramina on the cribriform plate and lodge filaments of the olfactory nerves.

The **Labyrinth** or **Lateral Mass** (*labyrinthus ethmoidalis*) consists of a number of thin-walled cellular cavities, the **ethmoidal cells**, arranged in three groups, *anterior, middle, and posterior*, and interposed between two vertical plates of bone; the lateral plate forms part of the orbit, the medial, part of the corresponding nasal cavity. In the disarticulated bone many of these cells are opened into, but when the bones are articulated, they are closed in at every part, except where they open into the nasal cavity.

Surfaces.—The **upper surface** of the labyrinth (Fig. 293) presents a number of half-broken cells, the walls of which are completed, in the articulated skull, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves, converted into canals by articulation with the frontal; they are the **anterior** and **posterior ethmoidal canals**, and open on the inner wall of the orbit. The **posterior surface** presents large irregular cellular cavities, which are closed in by articulation with the sphenoidal concha and orbital process of the palatine. The **lateral surface** (Fig. 296) is formed of a thin, smooth, oblong plate, the **lamina papyracea** (*os planum*), which covers in the middle and posterior ethmoidal cells

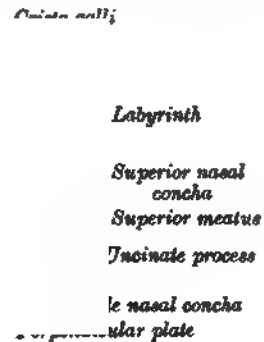

FIG. 295.—Ethmoidal bone from behind.

FIG. 296.—Ethmoidal bone from the right side.

and forms a large part of the medial wall of the orbit; it articulates above with the orbital plate of the frontal bone, below with the maxilla and orbital process of the palatine, in front with the lacrimal, and behind with the sphenoid.

In front of the lamina papyracea are some broken air cells which are overlapped and completed by the lacrimal bone and the frontal process of the maxilla. A curved lamina, the **uncinate process**, projects downward and backward from this part of the labyrinth; it forms a small part of the medial wall of the maxillary sinus, and articulates with the ethmoidal process of the inferior nasal concha.

The **medial surface** of the labyrinth (Fig. 297) forms part of the lateral wall of the corresponding nasal cavity. It consists of a thin lamella, which descends from the under surface of the cribriform plate, and ends below in a free, convoluted margin, the **middle nasal concha**. It is rough, and marked above by numerous grooves, directed nearly vertically downward from the cribriform plate; they lodge branches of the olfactory nerves, which are distributed to the mucous membrane covering the superior nasal concha. The back part of the surface is subdivided by a narrow oblique fissure, the **superior meatus** of the nose, bounded above by a thin, curved plate, the **superior nasal concha**; the posterior ethmoidal cells open into this meatus. Below, and in front of the superior meatus, is the convex

*Uncinate
process of
ethmoid*

*opens into
middle sinus
middle plate*

FIG. 297.—Lateral wall of nasal cavity, showing ethmoidal bone in position.

surface of the **middle nasal concha**; it extends along the whole length of the medial surface of the labyrinth, and its lower margin is free and thick. The lateral surface of the middle concha is concave, and assists in forming the **middle meatus** of the nose. The middle ethmoidal cells open into the central part of this meatus, and a sinuous passage, termed the **infundibulum**, extends upward and forward through the labyrinth and communicates with the anterior ethmoidal cells, and in about 50 per cent. of skulls is continued upward as the frontonasal duct into the frontal sinus.

Ossification.—The ethmoid is ossified in the cartilage of the nasal capsule by *three* centres: one for the perpendicular plate, and one for each labyrinth.

The labyrinths are first developed, ossific granules making their appearance in the region of the lamina papyracea between the fourth and fifth months of fetal life, and extending into the conchæ. At birth, the bone consists of the two labyrinths, which are small and ill-developed. During the first year after birth, the perpendicular plate and crista galli begin to ossify from a single centre, and are joined to the labyrinths about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the labyrinths. The development of the ethmoidal cells begins during fetal life.

Articulations.—The ethmoid articulates with *fifteen* bones: four of the cranium—the frontal, the sphenoid, and the two sphenoidal conchæ; and eleven of the face—the two nasals, two maxillæ, two lacrimals, two palatines, two inferior nasal conchæ, and the vomer.

Sutural or Wormian¹ Bones.—In addition to the usual centres of ossification of the cranium, others may occur in the course of the sutures, giving rise to irregular, isolated bones, termed *sutural* or *Wormian* bones. They occur most frequently in the course of the lambdoidal suture, but are occasionally seen at the fontanelles, especially the posterior. One, the *pterion ossicle*, sometimes exists between the sphenoidal angle of the parietal and the great wing of the sphenoid. They have a tendency to be more or less symmetrical on the two sides of the skull, and vary much in size. Their number is generally limited to two or three; but more than a hundred have been found in the skull of an adult hydrocephalic subject.

Applied Anatomy.—An arrest in the ossifying process may give rise to deficiencies, gaps, or fissures in the cranium, which are of importance from a medicolegal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins toward the centre of a bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become filled with thin laminae of bone. In many of these cases, however, the gaps must be regarded as due to absorption of bone already formed rather than as congenital deficiencies; this is especially the case when they appear in the centre of a bone such as the parietal, the ossification of which has already been described as occurring in a regular manner radiating from one centre. The condition is most commonly seen in very badly nourished children affected with congenital syphilis, and is called *craniotabes*.

THE FACIAL BONES (OSSA FACIEI).

The Nasal Bones (Ossa Nasalia).

The **nasal bones** are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face,

*Infraorbital
foram*

FIG. 298.—Articulation of nasal and lacrimal bones with maxilla.

and form, by their junction, “the bridge” of the nose (Fig. 334). Each has two surfaces and four borders.

¹ Ole Worm, Professor of Anatomy at Copenhagen, 1624–1639, was erroneously supposed to have given the first detailed description of these bones.

Surfaces.—The **outer surface** (Fig. 299) is concavoconvex from above downward, convex from side to side; it is covered by the Procerus and Compressor naris, and perforated about its centre by a foramen, for the transmission of a small vein. The **inner surface** (Fig. 300) is concave from side to side, and is traversed from above downward, by a groove for the passage of a branch of the nasociliary nerve.

Borders.—The **superior border** is narrow, thick, and serrated for articulation with the nasal notch of the frontal bone. The **inferior border** is thin, and gives attachment to the lateral cartilage of the nose; near its middle is a notch which marks the end of the groove just referred to. The **lateral border** is serrated, bevelled at the expense of the inner surface above, and of the outer below, to articulate with the frontal process of the maxilla. The **medial border**, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest, which forms part of the nasal septum: this crest articulates, from above downward, with the spine of the frontal, the perpendicular plate of the ethmoid, and the septal cartilage of the nose.

FIG. 299.—Right nasal bone. Outer surface.

FIG. 300.—Right nasal bone. Inner surface.

Ossification.—Each bone is ossified from *one* centre, which appears at the beginning of the third month of fetal life in the membrane overlying the front part of the cartilaginous nasal capsule.

Articulations.—The nasal articulates with four bones: two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the maxilla.

The Maxillæ (Upper Jaw).

The **maxillæ** are the largest bones of the face, excepting the mandible, and form, by their union, the whole of the upper jaw. Each assists in forming the boundaries of three cavities, viz., the roof of the mouth, the floor and lateral wall of the nose and the floor of the orbit; it also enters into the formation of two fossæ, the infratemporal and pterygopalatine, and two fissures, the inferior orbital and pterygomaxillary.

Each bone consists of a body and four processes—zygomatic, frontal, alveolar, and palatine.

The Body (*corpus maxillæ*).—The body is somewhat pyramidal in shape, and contains a large cavity, the **maxillary sinus** (*antrum of Highmore*). It has four surfaces—an anterior, a posterior or infratemporal, a superior or orbital, and a medial or nasal.

Surfaces.—The **anterior surface** (Fig. 301) is directed forward and lateralward. It presents at its lower part a series of eminences corresponding to the positions of the roots of the teeth. Just above those of the incisor teeth is a depression, the **incisive fossa**, which gives origin to the Depressor alae nasi; to the alveolar border below the fossa is attached a slip of the Orbicularis oris; above and a little lateral to it, the Nasalis arises. Lateral to the incisive fossa is another depression,

the **canine fossa**; it is larger and deeper than the incisive fossa, and is separated from it by a vertical ridge, the **canine eminence**, corresponding to the socket of the canine tooth; the canine fossa gives origin to the Caninus. Above the fossa is the **infraorbital foramen**, the end of the infraorbital canal; it transmits the infraorbital vessels and nerve. Above the foramen is the margin of the orbit, which affords attachment to part of the *Quadratus labii superioris*. Medially, the anterior surface is limited by a deep concavity, the **nasal notch**, the margin of which gives attachment to the *Dilatator naris posterior* and ends below in a pointed process, which with its fellow of the opposite side forms the **anterior nasal spine**.

Alveolar canals

Maxillary tuberosity

Canine. Premolars. Molars

FIG. 301.—Left maxilla. Outer surface.

The **infratemporal surface** (Fig. 301) is convex, directed backward and lateralward, and forms part of the infratemporal fossa. It is separated from the anterior surface by the zygomatic process and by a strong ridge, extending upward from the socket of the first molar tooth. It is pierced about its centre by the apertures of the **alveolar canals**, which transmit the posterior superior alveolar vessels and nerves. At the lower part of this surface is a rounded eminence, the **maxillary tuberosity**, especially prominent after the growth of the wisdom tooth; it is rough on its lateral side for articulation with the pyramidal process of the palatine bone and in some cases articulates with the lateral pterygoid plate of the sphenoid. It gives origin to a few fibres of the *Pterygoideus internus*. Immediately above this is a smooth surface, which forms the anterior boundary of the pterygopalatine fossa, and presents a groove, for the maxillary nerve; this groove is directed lateralward and slightly upward, and is continuous with the infraorbital groove on the orbital surface.

The **orbital surface** (Fig. 301) is smooth and triangular, and forms the greater part of the floor of the orbit. It is bounded *medially* by an irregular margin which in front presents a notch, the **lacrimal notch**; behind this notch the margin articulates with the lacrimal, the lamina papyracea of the ethmoid and the orbital process of the palatine. It is bounded *behind* by a smooth rounded edge which forms the anterior margin of the inferior orbital fissure, and sometimes articulates at its lateral extremity with the orbital surface of the great wing of the sphenoid.

It is limited *in front* by part of the circumference of the orbit, which is continuous medially with the frontal process, and laterally with the zygomatic process. Near the middle of the posterior part of the orbital surface is the **infraorbital groove**, for the passage of the infraorbital vessels and nerve. The groove begins at the middle of the posterior border, where it is continuous with that near the upper edge of the infratemporal surface, and, passing forward, ends in a canal, which subdivides into two branches. One of the canals, the **infraorbital canal**, opens just below the margin of the orbit; the other, which is smaller, runs downward in the substance of the anterior wall of the maxillary sinus, and transmits the anterior superior alveolar vessels and nerve to the front teeth of the maxilla. From the back part of the infraorbital canal, a second small canal is sometimes given off; it runs downward in the lateral wall of the sinus, and conveys the middle alveolar nerve to the premolar teeth. At the medial and forepart of the orbital surface, just lateral to the lacrimal groove, is a depression, which gives origin to the Obliquus oculi inferior.

anal*

FIG. 302 —Left maxilla. Nasal surface.

The **nasal surface** (Fig. 302) presents a large, irregular opening leading into the maxillary sinus. At the upper border of this aperture are some broken air cells, which, in the articulated skull, are closed in by the ethmoid and lacrimal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal cavity, and behind it is a rough surface for articulation with the perpendicular part of the palatine bone; this surface is traversed by a groove, commencing near the middle of the posterior border and running obliquely downward and forward; the groove is converted into a canal, the **pterygopalatine canal**, by the palatine bone. In front of the opening of the sinus is a deep groove, the **lacrimal groove**, which is converted into the nasolacrimal canal, by the lacrimal bone and inferior nasal concha; this canal opens into the inferior meatus of the nose and transmits the nasolacrimal duct. More anteriorly is an oblique ridge, the **conchal crest**, for articulation with the inferior nasal concha. The shallow concavity above this ridge forms part of the atrium of the middle meatus of the nose, and that below it, part of the inferior meatus.

The Maxillary Sinus or Antrum of Highmore (*sinus maxillaris*).—The maxillary sinus is a large pyramidal cavity, within the body of the maxilla: its **apex**, directed lateralward, is formed by the zygomatic process; its **base**, directed medialward, by the lateral wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the nasal orbital, anterior, and infratemporal surfaces of the body of the bone. Its **nasal wall**, or **base**, presents, in the disarticulated bone, a large, irregular aperture, communicating with the nasal cavity. In the articulated skull this aperture is much reduced in size by the following bones: the uncinat process of the ethmoid above, the ethmoidal process of the inferior nasal concha below, the vertical part of the palatine behind, and a small part of the lacrimal above and in front (Figs. 302, 303); the sinus communicates with the middle meatus of the nose, generally by two small apertures left between the above-mentioned bones. In the recent state, usually only one small opening exists, near the upper

FIG. 303.—Left maxillary sinus opened from the exterior.

part of the cavity; the other is closed by mucous membrane. On the **posterior wall** are the **alveolar canals**, transmitting the posterior superior alveolar vessels and nerves to the molar teeth. The **floor** is formed by the alveolar process of the maxilla, and, if the sinus be of an average size, is on a level with the floor of the nose; if the sinus be large it reaches below this level.

Projecting into the floor of the antrum are several conical processes, corresponding to the roots of the first and second molar teeth;¹ in some cases the floor is perforated by the fangs of the teeth. The infraorbital canal usually projects into the cavity as a well-marked ridge extending from the roof to the anterior wall; additional ridges are sometimes seen in the posterior wall of the cavity, and

¹ The number of teeth whose roots are in relation with the floor of the antrum is variable. The sinus "may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the *dens sapientiae*." (Salter)

are caused by the alveolar canals. The size of the cavity varies in different skulls, and even on the two sides of the same skull.¹

Applied Anatomy.—The extreme thinness of the walls of this cavity affords an explanation of the fact that a tumor growing from the maxillary sinus and encroaching upon the adjacent parts may push up the floor of the orbit, and displace the eyeball; may project into the nose; may protrude forward on to the cheek; or may make its way backward into the infratemporal fossa, or downward into the mouth.

The Zygomatic Process (*processus zygomaticus; malar process*).—The zygomatic process is a rough triangular eminence, situated at the angle of separation of the anterior, zygomatic, and orbital surfaces. *In front* it forms part of the anterior surface; *behind*, it is concave, and forms part of the infratemporal fossa; *above*, it is rough and serrated for articulation with the zygomatic bone; while *below*, it presents the prominent arched border which marks the division between the anterior and infratemporal surfaces.

The Frontal Process (*processus frontalis; nasal process*).—The frontal process is a strong plate, which projects upward, medialward, and backward, by the side of the nose, forming part of its lateral boundary. Its *lateral surface* is smooth, continuous with the anterior surface of the body, and gives attachment to the Quadratus labii superioris, the Orbicularis oculi, and the medial palpebral ligament. Its *medial surface* forms part of the lateral wall of the nasal cavity; at its upper part is a rough, uneven area, which articulates with the ethmoid, closing in the anterior ethmoidal cells; below this is an oblique ridge, the **ethmoidal crest**, the posterior end of which articulates with the middle nasal concha, while the anterior part is termed the **agger nasi**; the crest forms the upper limit of the atrium of the middle meatus. The *upper border* articulates with the frontal bone and the *anterior* with the nasal; the *posterior border* is thick, and hollowed into a groove, which is continuous below with the lacrimal groove on the nasal surface of the body: by the articulation of the medial margin of the groove with the anterior border of the lacrimal a corresponding groove on the lacrimal is brought into continuity, and together they form the **lacrimal fossa** for the lodgement of the lacrimal sac. The lateral margin of the groove is named the **anterior lacrimal crest**, and is continuous below with the orbital margin; at its junction with the orbital surface is a small tubercle, the **lacrimal tubercle**, which serves as a guide to the position of the lacrimal sac.

The Alveolar Process (*processus alveolaris*).—The alveolar process is the thickest and most spongy part of the bone. It is broader behind than in front, and excavated into deep cavities for the reception of the teeth. These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and are subdivided into minor cavities by septa; those for the incisors are single, but deep and narrow. The Buccinator arises from the outer surface of this process, as far forward as the first molar tooth. When the maxillæ are articulated with each other, their alveolar processes together form the **alveolar arch**; the centre of the anterior margin of this arch is named the **alveolar point**.

The Palatine Process (*processus palatinus; palatal process*).—The palatine process, thick and strong, is horizontal and projects medialward from the nasal surface of the bone. It forms a considerable part of the floor of the nose and the roof of the mouth and is much thicker in front than behind. Its *inferior surface* (Fig. 304) is concave, rough and uneven, and forms, with the palatine process of the opposite bone, the anterior three-fourths of the hard plate. It is perforated by numerous foramina for the passage of the nutrient vessels; is channelled at the

¹ Aldren Turner (*op. cit.*) gives the following measurements as those of an average sized sinus: vertical height opposite first molar tooth, 1½ inch; transverse breadth, 1 inch; and antero-posterior depth, 1¼ inch.

back part of its lateral border by a groove, sometimes a canal, for the transmission of the descending palatine vessels and the anterior palatine nerve from the sphenopalatine ganglion; and presents little depressions for the lodgement of the palatine glands. When the two maxillæ are articulated, a funnel-shaped opening, the **incisive foramen**, is seen in the middle line, immediately behind the incisor teeth. In this opening the orifices of two lateral canals are visible; they are named the **incisive canals** or **foramina of Stensen**; through each of them passes the terminal branch of the descending palatine artery and the nasopalatine nerve. Occasionally two additional canals are present in the middle line; they are termed the **foramina of Scarpa**, and when present transmit the nasopalatine nerves, the left passing through the anterior, and the right through the posterior canal. On the under surface of the palatine process, a delicate linear suture, well seen in young skulls, may sometimes be noticed extending lateralward and forward on either side from

Incisive canals

the incisive foramen to the interval between the lateral incisor and the canine tooth. The small part in front of this suture constitutes the **premaxilla** (*os incisivum*), which in most vertebrates forms an independent bone; it includes the whole thickness of the alveolus, the corresponding part of the floor of the nose and the anterior nasal spine, and contains the sockets of the incisor teeth. The upper surface of the palatine process is concave from side to side, smooth, and forms the greater part of the floor of the nasal cavity. It presents, close to its medial margin, the upper orifice of the incisive canal. The lateral border of the process is incorporated with the rest of the bone. The medial border is thicker in front than behind, and is raised above into a ridge, the **nasal crest**, which, with the corresponding ridge of the opposite bone, forms a groove for the reception of the vomer. The front part of this ridge rises to a considerable height, and is named the **incisor crest**; it is prolonged forward into a sharp process, which forms, together with a similar

process of the opposite bone, the *anterior nasal spine*. The *posterior border* is serrated for articulation with the horizontal part of the palatine bone.

Ossification.—The maxilla is ossified in membrane. Mall¹ and Fawcett² maintain that it is ossified from *two* centres only, one for the maxilla proper and one for the premaxilla. These centres appear during the sixth week of fetal life and unite in the beginning of the third month, but the suture between the two portions persists on the palate until nearly middle life. Mall states that the frontal process is developed from both centres. The maxillary sinus appears as a shallow groove on the nasal surface of the bone about the fourth month of fetal life, but does not reach its full size until after the second dentition. The maxilla was formerly described as ossifying from six centres, viz., one, the *orbitonasal*, forms that portion of the body of the bone which lies medial to the infraorbital canal, including the medial part of the floor of the orbit and the lateral wall of the nasal cavity; a second, the *zygomatic*, gives origin to the portion which lies lateral to the infraorbital canal, including the zygomatic process; from a third, the *palatine*, is developed the palatine process posterior to the incisive canal together with the adjoining part of the nasal wall; a fourth, the *premaxillary*, forms the incisive bone which carries the incisor

FIG. 305.—Anterior surface of maxilla at birth.

FIG. 306.—Inferior surface of maxilla at birth.

ry sinus

Palatine process

FIG. 307.—Nasal surface of maxilla at birth.

teeth and corresponds to the premaxilla of the lower vertebrates;³ a fifth, the *nasal*, gives rise to the frontal process and the portion above the canine tooth; and a sixth, the *infravomerine*, lies between the palatine and premaxillary centres and beneath the vomer; this centre, together with the corresponding centre of the opposite bone, separates the incisive canals from each other.

Articulations.—The maxilla articulates with *nine* bones: two of the cranium, the frontal and ethmoid, and seven of the face, viz., the nasal, zygomatic, lacrimal, inferior nasal concha, palatine, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital surface, and sometimes with the lateral pterygoid plate of the sphenoid.

CHANGES PRODUCED IN THE MAXILLA BY AGE.

At birth the transverse and antero-posterior diameters of the bone are each greater than the vertical. The frontal process is well-marked and the body of the bone consists of little more than the alveolar process, the teeth sockets reaching almost to the floor of the orbit. The maxillary sinus presents the appearance of a furrow on the lateral wall of the nose. In the adult the vertical diameter is the greatest, owing to the development of the alveolar process and the increase in size of the sinus. In old age the bone reverts in some measure to the infantile condition; its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and reduced in thickness.

¹ American Journal of Anatomy, 1906, vol. v.

² Journal of Anatomy and Physiology, 1911, vol. xlv.

³ Some anatomists believe that the premaxillary bone is ossified by two centres (see page 299).

The Lacrimal Bone (*Os Lacrimale*).

The **lacrimal bone**, the smallest and most fragile bone of the face, is situated at the front part of the medial wall of the orbit (Fig. 309). It has two surfaces and four borders.

Surfaces.—The **lateral or orbital surface** (Fig. 308) is divided by a vertical ridge, the **posterior lacrimal crest**, into two parts. In front of this crest is a longitudinal groove, the **lacrimal sulcus** (*sulcus lacrimalis*), the inner margin of which unites with the frontal process of the maxilla, and the lacrimal fossa is thus completed. The upper part of this fossa lodges the lacrimal sac, the lower part, the nasolacrimal duct. The portion behind the crest is smooth, and forms part of the medial wall of the orbit. The crest, with a part of the orbital surface immediately behind it, gives origin to the lacrimal part of the *Orbicularis oculi* and ends below in a small, hook-like projection, the **lacrimal hamulus**, which articulates with the lacrimal tubercle of the maxilla, and completes the upper orifice of the lacrimal canal; it sometimes exists as a separate piece, and is then called the **lesser lacrimal bone**.

The **medial or nasal surface** presents a longitudinal furrow, corresponding to the crest on the lateral surface. The area in front of this furrow forms part of the middle meatus of the nose; that behind it articulates with the ethmoid, and completes some of the anterior ethmoidal cells.

Borders.—Of the **four borders** the **anterior** articulates with the frontal process of the maxilla; the **posterior** with the lamina papyracea of the ethmoid; the **superior** with the frontal bone. The **inferior** is divided by the lower edge of the posterior lacrimal crest into two parts: the posterior part articulates with the orbital plate of the maxilla; the anterior is prolonged downward as the **descending process**, which articulates with the lacrimal process of the inferior nasal concha, and assists in forming the canal for the nasolacrimal duct.

Ossification.—The lacrimal is ossified from a single centre, which appears about the twelfth week in the membrane covering the cartilaginous nasal capsule.

Articulations.—The lacrimal articulates with **four bones**: two of the cranium, the frontal and ethmoid, and two of the face, the maxilla and the inferior nasal concha.

The Zygomatic Bone (*Os Zygomaticum*; **Malar Bone**).

The **zygomatic bone** is small and quadrangular, and is situated at the upper and lateral part of the face: it forms the prominence of the cheek, part of the lateral wall and floor of the orbit, and parts of the temporal and infratemporal fossae (Fig. 309). It presents a malar and a temporal surface; four processes, the frontosphenoidal, orbital, maxillary, and temporal; and four borders.

Surfaces.—The **malar surface** (Fig. 310) is convex and perforated near its centre by a small aperture, the **zygomaticofacial foramen**, for the passage of the zygomaticofacial nerve and vessels; below this foramen is a slight elevation, which gives origin to the *Zygomaticus*.

The **temporal surface** (Fig. 311), directed backward and medialward, is concave, presenting medially a rough, triangular area, for articulation with the maxilla, and laterally a smooth, concave surface, the upper part of which forms the anterior boundary of the temporal fossa, the lower a part of the infratemporal fossa. Near the centre of this surface is the **zygomaticotemporal foramen** for the transmission of the zygomaticotemporal nerve.

Infer. nasal concha
Fig. 308. —Left lacrimal bone. Orbital surface. Enlarged.

Processes.—The **frontosphenoidal process** is thick and serrated, and articulates with the zygomatic process of the frontal bone. On its orbital surface, just within the orbital margin and about 11 mm. below the zygomaticofrontal suture is a tubercle of varying size and form, but present in 95 per cent. of skulls (Whitnall¹).

FIG. 309.—Left zygomatic bone *in situ*

The **orbital process** is a thick, strong plate, projecting backward and medialward from the orbital margin. Its *antero-medial surface* forms, by its junction with the orbital surface of the maxilla and with the great wing of the sphenoid, part of the floor and lateral wall of the orbit. On it are seen the orifices of two canals,

With Frontal

FIG. 310.—Left zygomatic bone Malar surface

FIG. 311.—Left zygomatic bone. Temporal surface.

the **zygomatico-orbital foramina**; one of these canals opens into the temporal fossa, the other on the malar surface of the bone; the former transmits the zygomatico-temporal, the latter the zygomaticofacial nerve. Its *postero-lateral surface*, smooth

¹Journal of Anatomy and Physiology, vol. xiv. The structures attached to this tubercle are: (1) the check ligament of the Rectus lateralis; (2) the lateral end of the aponeurosis of the Levator palpebrae superioris; (3) the suspensory ligament of the eye (Lockwood), and (4) the lateral extremities of the superior and inferior tarsal.

and convex, forms parts of the temporal and infratemporal fossæ. Its *anterior margin*, smooth and rounded, is part of the circumference of the orbit. Its *superior margin*, rough, and directed horizontally, articulates with the frontal bone behind the zygomatic process. Its *posterior margin* is serrated for articulation, with the great wing of the sphenoid and the orbital surface of the maxilla. At the angle of junction of the sphenoidal and maxillary portions, a short, concave, non-articular part is generally seen; this forms the anterior boundary of the inferior orbital fissure: occasionally, this non-articular part is absent, the fissure then being completed by the junction of the maxilla and sphenoid, or by the interposition of a small sutural bone in the angular interval between them. The **maxillary process** presents a rough, triangular surface which articulates with the maxilla. The **temporal process**, long, narrow, and serrated, articulates with the zygomatic process of the temporal.

Borders.—The **antero-superior** or **orbital border** is smooth, concave, and forms a considerable part of the circumference of the orbit. The **antero-inferior** or **maxillary border** is rough, and bevelled at the expense of its inner table, to articulate with the maxilla; near the orbital margin it gives origin to the *Quadratus labii superioris*. The **postero-superior** or **temporal border**, curved like an italic letter *f*, is continuous above with the commencement of the temporal line, and below with the upper border of the zygomatic arch; the temporal fascia is attached to it. The **postero-inferior** or **zygomatic border** affords attachment by its rough edge to the *Masseter*.

Ossification.—The zygomatic bone is generally described as ossifying from three centres—one for the malar and two for the orbital portion; these appear about the eighth week and fuse about the fifth month of fetal life. Mall describes it as being ossified from one centre which appears just beneath and to the lateral side of the orbit. After birth, the bone is sometimes divided by a horizontal suture into an upper larger, and a lower smaller division. In some quadrumana the zygomatic bone consists of two parts, an orbital and a malar.

Articulations.—The zygomatic articulates with *four* bones: the frontal, sphenoidal, temporal, and maxilla.

FIG. 312.—Articulation of left palatine bone with maxilla.

The Palatine Bone (Os Palatinum; Palate Bone).

The **palatine bone** is situated at the back part of the nasal cavity between the maxilla and the pterygoid process of the sphenoid (Fig. 312). It contributes to the walls of three cavities: the floor and lateral wall of the nasal cavity, the

roof of the mouth, and the floor of the orbit; it enters into the formation of two fossæ, the **pterygopalatine** and **pterygoid fossæ**; and one fissure, the **inferior orbital fissure**. The palatine bone somewhat resembles the letter L, and consists of a horizontal and a vertical part and three outstanding processes—viz., the pyramidal process, which is directed backward and lateralward from the junction of the two parts, and the orbital and sphenoidal processes, which surmount the vertical part, and are separated by a deep notch, the sphenopalatine notch.

The Horizontal Part (*pars horizontalis*; *horizontal plate*) (Figs. 313, 314).—The horizontal part is quadrilateral, and has two surfaces and four borders.

Surfaces.—The **superior surface**, concave from side to side, forms the back part of the floor of the nasal cavity. The **inferior surface**, slightly concave and rough, forms, with the corresponding surface of the opposite bone, the posterior fourth of the hard palate. Near its posterior margin may be seen a more or less marked transverse ridge for the attachment of part of the aponeurosis of the Tensor veli palatini.

FIG. 313.—Left palatine bone. Nasal aspect. Enlarged.

FIG. 314.—Left palatine bone. Posterior aspect. Enlarged.

Borders.—The **anterior border** is serrated, and articulates with the palatine process of the maxilla. The **posterior border** is concave, free, and serves for the attachment of the soft palate. Its medial end is sharp and pointed, and, when united with that of the opposite bone, forms a projecting process, the **posterior nasal spine** for the attachment of the *Musculus uvulae*. The **lateral border** is united with the lower margin of the perpendicular part, and is grooved by the lower end of the pterygopalatine canal. The **medial border**, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the ridge of the opposite bone, forms the **nasal crest** for articulation with the posterior part of the lower edge of the vomer.

The Vertical Part (*pars perpendicularis*; *perpendicular plate*) (Figs. 313, 314).—The vertical part is thin, of an oblong form, and presents two surfaces and four borders.

Surfaces.—The **nasal surface** exhibits at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this is a well-marked horizontal ridge, the **conchal crest**, for articulation with the inferior nasal concha; still higher is a second broad, shallow depression, which

forms part of the middle meatus, and is limited above by a horizontal crest less prominent than the inferior, the **ethmoidal crest**, for articulation with the middle nasal concha. Above the ethmoidal crest is a narrow, horizontal groove, which forms part of the superior meatus.

The **maxillary surface** is rough and irregular throughout the greater part of its extent, for articulation with the nasal surface of the maxilla; its upper and back part is smooth where it enters into the formation of the pterygopalatine fossa; it is also smooth in front, where it forms the posterior part of the medial wall of the maxillary sinus. On the posterior part of this surface is a deep vertical groove, converted into the **pterygopalatine canal**, by articulation with the maxilla; this canal transmits the descending palatine vessels, and the anterior palatine nerve.

Borders.—The **anterior border** is thin and irregular; opposite the conchal crest is a pointed, projecting lamina, the **maxillary process**, which is directed forward, and closes in the lower and back part of the opening of the maxillary sinus. The **posterior border** (Fig. 314) presents a deep groove, the edges of which are serrated for articulation with the medial pterygoid plate of the sphenoid. This border is continuous above with the sphenoidal process; below it expands into the pyramidal process. The **superior border** supports the orbital process in front and the sphenoidal process behind. These processes are separated by the **sphenopalatine notch**, which is converted into the **sphenopalatine foramen** by the under surface of the body of the sphenoid. In the articulated skull this foramen leads from the pterygopalatine fossa into the posterior part of the superior meatus of the nose, and transmits the sphenopalatine vessels and the superior nasal and nasopalatine nerves. The **inferior border** is fused with the lateral edge of the horizontal part, and immediately in front of the pyramidal process is grooved by the lower end of the pterygopalatine canal.

The Pyramidal Process or Tuberosity (*processus pyramidalis*).—The pyramidal process projects backward and lateralward from the junction of the horizontal and vertical parts, and is received into the angular interval between the lower extremities of the pterygoid plates. On its **posterior surface** is a smooth, grooved, triangular area, limited on either side by a rough articular furrow. The furrows articulate with the pterygoid plates, while the grooved intermediate area completes the lower part of the pterygoid fossa and gives origin to a few fibres of the Pterygoideus internus. The anterior part of the **lateral surface** is rough, for articulation with the tuberosity of the maxilla; its posterior part consists of a smooth triangular area which appears, in the articulated skull, between the tuberosity of the maxilla and the lower part of the lateral pterygoid plate, and completes the lower part of the infratemporal fossa. On the **base** of the pyramidal process, close to its union with the horizontal part, are the lesser palatine foramina for the transmission of the posterior and middle palatine nerves.

The Orbital Process (*processus orbitalis*).—The orbital process is placed on a higher level than the sphenoidal, and is directed upward and lateralward from the front of the vertical part, to which it is connected by a constricted neck. It presents five surfaces, which enclose an air cell. Of these surfaces, three are articular and two non-articular. The articular surfaces are: (1) the **anterior** or **maxillary**, directed forward, lateralward, and downward, of an oblong form, and rough for articulation with the maxilla; (2) the **posterior** or **sphenoidal**, directed backward, upward, and medialward; it presents the opening of the air cell, which usually communicates with the sphenoidal sinus; the margins of the opening are serrated for articulation with the sphenoidal concha; (3) the **medial** or **ethmoidal**, directed forward, articulates with the labyrinth of the ethmoid. In some cases the air cell opens on this surface of the bone and then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates with the posterior ethmoidal cells and the sphenoidal sinus. The non-articular

surfaces are: (1) the **superior** or **orbital**, directed upward and lateralward; it is triangular in shape, and forms the back part of the floor of the orbit; and (2) the **lateral**, of an oblong form, directed toward the pterygopalatine fossa; it is separated from the orbital surface by a rounded border, which enters into the formation of the inferior orbital fissure.

The Sphenoidal Process (*processus sphenoidalis*).—The sphenoidal process is a thin, compressed plate, much smaller than the orbital, and directed upward and medialward. It presents three surfaces and two borders. The **superior surface** articulates with the root of the pterygoid process and the under surface of the sphenoidal concha, its medial border reaching as far as the ala of the vomer; it presents a groove which contributes to the formation of the pharyngeal canal. The **medial surface** is concave, and forms part of the lateral wall of the nasal cavity. The **lateral surface** is divided into an articular and a non-articular portion: the former is rough, for articulation with the medial pterygoid plate; the latter is smooth, and forms part of the pterygopalatine fossa. The **anterior border** forms the posterior boundary of the sphenopalatine notch. The **posterior border**, serrated at the expense of the outer table, articulates with the medial pterygoid plate.

The orbital and sphenoidal processes are separated from one another by the **sphenopalatine notch**. Sometimes the two processes are united above, and form between them a complete foramen (Fig. 313), or the notch may be crossed by one or more spicules of bone, giving rise to two or more foramina.

Ossification.—The palatine bone is ossified in membrane from a single centre, which makes its appearance about the sixth or eighth week of fetal life at the angle of junction of the two parts of the bone. From this point ossification spreads medialward to the horizontal part, downward into the pyramidal process, and upward into the vertical part. Some authorities describe the bone as ossifying from four centres: one for the pyramidal process and portion of the vertical part behind the pterygopalatine groove; a second for the rest of the vertical and the horizontal parts; a third for the orbital, and a fourth for the sphenoidal process. At the time of birth the height of the vertical part is about equal to the transverse width of the horizontal part, whereas in the adult the former measures about twice as much as the latter.

Articulations.—The palatine articulates with six bones: the sphenoid, ethmoid, maxilla, inferior nasal concha, vomer, and opposite palatine.

The Inferior Nasal Concha (Concha Nasalis Inferior; Inferior Turbinate Bone).

The **inferior nasal concha** extends horizontally along the lateral wall of the nasal cavity (Fig. 315) and consists of a lamina of spongy bone, curled upon itself like a scroll. It has two surfaces, two borders, and two extremities.

The **medial surface** (Fig. 316) is convex, perforated by numerous apertures, and traversed by longitudinal grooves for the lodgement of vessels. The **lateral surface** is concave (Fig. 317), and forms part of the inferior meatus. Its **upper border** is thin, irregular, and connected to various bones along the lateral wall of the nasal cavity. It may be divided into three portions: of these, the anterior articulates with the conchal crest of the maxilla; the posterior with the conchal crest of the palatine; the middle portion presents three well-marked processes, which vary much in their size and form. Of these, the anterior or **lacrimal process** is small and pointed and is situated at the junction of the anterior fourth with the posterior three-fourths of the bone: it articulates, by its apex, with the descending process of the lacrimal bone, and, by its margins, with the groove on the back of the frontal process of the maxilla, and thus assists in forming the canal for the nasolacrimal duct. Behind this process a broad, thin plate, the **ethmoidal process**, ascends to join the uncinat process of the ethmoid; from its lower border a thin lamina, the **maxillary process**, curves downward and lateralward; it articulates with the maxilla and forms a part of the medial wall of the maxillary sinus. The **inferior border** is free, thick, and cellular in structure, more especially in the middle

of the bone. Both **extremities** are more or less pointed, the posterior being the more tapering.

FIG. 315.—Lateral wall of right nasal cavity showing inferior concha *in situ*.

Ossification.—The inferior nasal concha is ossified from a single centre, which appears about the fifth month of fetal life in the lateral wall of the cartilaginous nasal capsule.

Articulations.—The inferior nasal concha articulates with *four* bones: the ethmoid, maxilla, lacrimal, and palatine.

FIG. 316.—Right inferior nasal concha.
Medial surface.

FIG. 317.—Right inferior nasal concha.
Lateral surface.

The Vomer.

The **vomer** is situated in the median plane, but its anterior portion is frequently bent to one or other side. It is thin, somewhat quadrilateral in shape, and forms the hinder and lower part of the nasal septum (Fig. 318); it has two surfaces and four borders. The **surfaces** (Fig. 319) are marked by small furrows for blood-vessels, and on each is the **nasopalatine groove**, which runs obliquely downward and forward, and lodges the nasopalatine nerve and vessels. The **superior border**, the thickest, presents a deep furrow, bounded on either side by a horizontal projecting ala of bone; the furrow receives the rostrum of the sphenoid, while the

margins of the *alæ* articulate with the vaginal processes of the medial pterygoid plates of the sphenoid behind, and with the sphenoidal processes of the palatine bones in front. The **inferior border** articulates with the crest formed by the maxillæ and palatine bones. The **anterior border** is the longest and slopes downward and

forward. Its upper half is fused with the perpendicular plate of the ethmoid; its lower half is grooved for the inferior margin of the septal cartilage of the nose. The **posterior border** is free, concave, and separates the choanæ. It is thick and bifid above, thin below.

FIG. 319.—The vomer

Ossification.—At an early period the septum of the nose consists of a plate of cartilage, the *ethmiovomerine cartilage*. The postero-superior part of this cartilage is ossified to form the perpendicular plate of the ethmoid; its antero-inferior portion persists as the septal cartilage, while the vomer is ossified in the membrane covering its postero-inferior part. Two ossific centres, one on either side of the middle line, appear about the eighth week of fetal life in this part of the membrane, and hence the vomer consists primarily of two lamellæ. About the third month these unite below, and thus a deep groove

is formed in which the cartilage is lodged. As growth proceeds, the union of the lamellæ extends upward and forward, and at the same time the intervening plate of cartilage undergoes absorption. By the age of puberty the lamellæ are almost completely united to form a median plate, but evidence of the bilaminar origin of the bone is seen in the everted *alæ* of its upper border and the groove on its anterior margin.

Articulations.—The vomer articulates with six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the two maxillæ and the two palatine bones; it also articulates with the septal cartilage of the nose.

Applied Anatomy.—The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, little, if any, submucous connective tissue intervening. Hence polypi are rarely found growing from this surface, though they frequently grow from the lateral walls of the nasal cavities, where the submucous tissue is abundant.

The Mandible (Mandibula; Inferior Maxillary Bone; Lower Jaw).

The **mandible**, the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the **body**, and two perpendicular portions, the **rami**, which unite with the ends of the body nearly at right angles.

The Body (*corpus mandibulæ*).—The body is curved somewhat like a horseshoe, and has two surfaces and two borders.

Coronoid process

Condyle

*Mental
protuberance*

maxillary artery

FIG. 320.—Mandible. Outer surface. Side view

Surfaces.—The **external surface** (Fig. 320) is marked in the median line by a faint ridge, indicating the **symphysis** or line of junction of the two pieces of which the bone is composed at an early period of life. This ridge divides below and encloses a triangular eminence, the **mental protuberance**, the base of which is depressed in the centre but raised on either side to form the **mental tubercle**. On either side of the symphysis, just below the incisor teeth, is a depression, the **incisive fossa**, which gives origin to the Mentalis and a small portion of the Orbicularis oris. Below the second premolar tooth, on either side, midway between the upper and lower borders of the body, is the **mental foramen**, for the passage of the mental vessels and nerve. Running backward and upward from each mental tubercle is a faint ridge, the **oblique line**, which is continuous with the anterior border of the ramus; it affords attachment to the Quadratus labii inferioris and Triangularis; the Platysma is attached below it.

The **internal surface** (Fig. 321) is concave from side to side. Near the lower part of the symphysis is a pair of laterally placed spines, termed the **mental spines**, which give origin to the Genioglossi. Immediately below these is a second pair of spines, or more frequently a median ridge or impression, for the origin of the

Geniohyoidei. In some cases the mental spines are fused to form a single eminence, in others they are absent and their position is indicated merely by an irregularity of the surface. Above the mental spines a median foramen and furrow are sometimes seen; they mark the line of union of the halves of the bone. Below the mental spines, on either side of the middle line, is an oval depression for the attachment of the anterior belly of the Digastricus. Extending upward and backward on either side from the lower part of the symphysis is the **mylohyoid line**, which gives origin to the Mylohyoideus; the posterior part of this line, near the alveolar margin, gives attachment to a small part of the Constrictor pharyngis superior, and to the pterygomandibular raphé. Above the anterior part of this line is a smooth triangular area against which the sublingual gland rests, and below the hinder part, an oval fossa for the submaxillary gland.

BODY

FIG. 321.—Mandible. Inner surface. Side view.

Borders.—The **superior** or **alveolar border**, wider behind than in front, is hollowed into cavities, for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To the outer lip of the superior border, on either side, the Buccinator is attached as far forward as the first molar tooth. The **inferior border** is rounded, longer than the superior, and thicker in front than behind; at the point where it joins the lower border of the ramus a shallow groove; for the external maxillary artery, may be present.

The Ramus (*ramus mandibulae; perpendicular portions*).—The ramus is quadrilateral in shape, and has two surfaces, four borders, and two processes.

Surfaces.—The **lateral surface** (Fig. 320) is flat and marked by oblique ridges at its lower part; it gives attachment throughout nearly the whole of its extent to the Masseter. The **medial surface** (Fig. 321) presents about its centre the oblique **mandibular foramen**, for the entrance of the inferior alveolar vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the **lingula mandibulae**, which gives attachment to the sphenomandibular ligament; at its lower and back part is a notch from which the **mylohyoid groove** runs obliquely downward and forward, and lodges the mylohyoid vessels and nerve. Behind this groove is a rough surface, for the insertion

of the Pterygoideus internus. The **mandibular canal** runs obliquely downward and forward in the ramus, and then horizontally forward in the body, where it is placed under the alveoli and communicates with them by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals which run to the cavities containing the incisor teeth. In the posterior two-thirds of the bone the canal is situated nearer the internal surface of the mandible; and in the anterior third, nearer its external surface. It contains the inferior alveolar vessels and nerve, from which branches are distributed to the teeth. The **lower border** of the ramus is thick, straight, and continuous with the inferior border of the body of the bone. At its junction with the posterior border is the **angle of the mandible**, which may be either inverted or everted and is marked by rough, oblique ridges on each side, for the attachment of the Masseter laterally, and the Pterygoideus internus medially; the stylomandibular ligament is attached to the angle between these muscles. The **anterior border** is thin above, thicker below, and continuous with the oblique line. The **posterior border** is thick, smooth, rounded, and covered by the parotid gland. The **upper border** is thin, and is surmounted by two processes, the **coronoid** in front and the **condyloid** behind, separated by a deep concavity, the **mandibular notch**.

The **Coronoid Process** (*processus coronoideus*) is a thin, triangular eminence, which is flattened from side to side and varies in shape and size. Its **anterior border** is convex and is continuous below with the anterior border of the ramus; its **posterior border** is concave and forms the anterior boundary of the mandibular notch. Its **lateral surface** is smooth, and affords insertion to the Temporalis and Masseter. Its **medial surface** gives insertion to the Temporalis, and presents a ridge which begins near the apex of the process and runs downward and forward to the inner side of the last molar tooth. Between this ridge and the anterior border is a grooved triangular area, the upper part of which gives attachment to the Temporalis, the lower part to some fibres of the Buccinator.

The **Condyloid Process** (*processus condyloideus*) is thicker than the coronoid, and consists of two portions: the **condyle**, and the constricted portion which supports it, the **neck**. The **condyle** presents an articular surface for articulation with the articular disk of the temporomandibular joint; it is convex from before backward and from side to side, and extends farther on the posterior than on the anterior surface. Its long axis is directed medialward and slightly backward, and if prolonged to the middle line will meet that of the opposite condyle near the anterior margin of the foramen magnum. At the lateral extremity of the condyle is a small tubercle for the attachment of the temporomandibular ligament. The **neck** is flattened from before backward, and strengthened by ridges which descend from the forepart and sides of the condyle. Its posterior surface is convex; its anterior presents a depression for the attachment of the Pterygoideus externus.

The **mandibular notch**, separating the two processes, is a deep semilunar depression, and is crossed by the masseteric vessels and nerve.

Ossification.—The mandible is ossified in the fibrous membrane covering the outer surfaces of Meckel's cartilages. These cartilages form the cartilaginous bar of the mandibular arch (see p. 109), and are two in number, a right and a left. Their proximal or cranial ends are connected with the ear capsules, and their distal extremities are joined to one another at the symphysis by mesodermal tissue. They run forward immediately below the condyles and then, bending downward, lie in a groove near the lower border of the bone; in front of the canine tooth they incline upward to the symphysis. From the proximal end of each cartilage the malleus and incus, two of the bones of the middle ear, are developed; the next succeeding portion, as far as the lingula, is replaced by fibrous tissue, which persists to form the sphenomandibular ligament. Between the lingula and the canine tooth the cartilage disappears, while the portion of it below and behind the incisor teeth becomes ossified and incorporated with this part of the mandible.

Ossification takes place in the membrane covering the outer surface of the ventral end of Meckel's cartilage (Figs. 322 to 325), and each half of the bone is formed from a single centre

which appears, near the mental foramen, about the sixth week of fetal life. By the tenth week the portion of Meckel's cartilage which lies below and behind the incisor teeth is surrounded and invaded by the membrane bone. Somewhat later, accessory nuclei of cartilage make their appear-

FIG. 322.—Mandible of human embryo of 24 mm. long. Outer aspect. (From model by Low.)

ance, viz., a wedge-shaped nucleus in the condyloid process and extending downward through the ramus; a small strip along the anterior border of the coronoid process; and smaller nuclei in the front part of both alveolar walls and along the front of the lower border of the bone. These accessory nuclei possess no separate ossific centres, but are invaded by the surrounding membrane

Mandibular nerve

Me.

bone and undergo absorption. The inner alveolar border, usually described as arising from a separate ossific centre (*splenic centre*), is formed in the human mandible by an ingrowth from the main mass of the bone. At birth the bone consists of two parts, united by a fibrous symphysis, in which ossification takes place during the first year.

Auriculotemporal nerve

The foregoing description of the ossification of the mandible is based on the researches of Low¹ and Fawcett,² and differs somewhat from that usually given.

Articulations.—The mandible articulates with the two temporal bones.

¹ Proceedings of the Anatomical and Anthropological Society of the University of Aberdeen, 1905, and Journal of Anatomy and Physiology, vol. xlv.

² Journal of the American Medical Association, September 2, 1905.

CHANGES PRODUCED IN THE MANDIBLE BY AGE.

At birth (Fig. 326), the body of the bone is a mere shell, containing the sockets of the two incisor, the canine, and the two deciduous molar teeth, imperfectly partitioned off from one another. The mandibular canal is of large size, and runs near the lower border of the bone; the mental foramen opens beneath the socket of the first deciduous molar tooth. The angle is obtuse (175°), and the condyloid portion is nearly in line with the body. The coronoid process is of comparatively large size, and projects above the level of the condyle.

After birth (Fig. 327), the two segments of the bone become joined at the symphysis, from below upward, in the first year; but a trace of separation may be visible in the beginning of the second year, near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body increases owing to increased growth of the alveolar part, to afford room for the roots of the teeth, and by thickening of the subdental portion which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The mandibular canal, after the second dentition, is situated just above the level of the mylohyoid line; and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth; about the fourth year it is 140° .

In the adult (Fig. 328), the alveolar and subdental portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower borders of the bone, and the mandibular canal runs nearly parallel with the mylohyoid line. The ramus is almost vertical in direction, the angle measuring from 110° to 120° .

In old age (Fig. 329), the bone becomes greatly reduced in size, for with the loss of the teeth the alveolar process is absorbed, and, consequently, the chief part of the bone is below the oblique line. The mandibular canal, with the mental foramen opening from it, is close to the alveolar border. The ramus is oblique in direction, the angle measures about 140° , and the neck of the condyle is more or less bent backward.

The Hyoid Bone (*Os Hyoideum*; *Lingual Bone*).

The hyoid bone is shaped like a horseshoe, and is suspended from the tips of the styloid processes of the temporal bones by the stylohyoid ligaments. It consists of five segments, viz., a body, two greater cornua, and two lesser cornua.

The Body or Basihyal (*corpus oss. hyoidei*).—The body or central part is of a quadrilateral form. Its **anterior surface** (Fig. 330) is convex and directed forward and upward. It is crossed in its upper half by a well-marked transverse ridge with a slight downward convexity, and in many cases a vertical median ridge divides it into two lateral halves. The portion of the vertical ridge above the transverse line is present in a majority of specimens, but the lower portion is evident only in rare cases. The anterior surface gives insertion to the Geniohyoideus in the greater part of its extent both above and below the transverse ridge; a portion of the origin of the Hyoglossus notches the lateral margin of the Geniohyoideus attachment. Below the transverse ridge the Mylohyoideus, Sternohyoideus, and Omohyoides are inserted. The **posterior surface** is smooth, concave, directed backward and downward, and separated from the epiglottis by the hyothyroid membrane and a quantity of loose areolar tissue; a bursa intervenes between it and the hyothyroid membrane. The **superior border** is rounded, and gives attachment to the hyothyroid membrane and some aponeurotic fibres of the Genioglossus. The **inferior border** affords insertion medially to the Sternohyoideus and laterally to the Omohyoides and occasionally a portion of the Thyreohyoideus. It also gives attachment to the Levator glandulae thyreoideae, when this muscle is present. In early life the **lateral borders** are connected to the greater cornua by synchondroses; after middle life usually by bony union.

The Greater Cornua or Thyrohyals (*cornua majora*).—The greater cornua project backward from the lateral borders of the body; they are flattened from above downward and diminish in size from before backward; each ends in a tubercle to which is fixed the lateral hyothyroid ligament. The **upper surface** is rough

FIG. 326. — At birth.

FIG. 329. — In old age.
Side view of the mandible at different periods of life.

close to its lateral border, for muscular attachments: the largest of these are the origins of the Hyoglossus and Constrictor pharyngis medius which extend along the whole length of the cornu; the Digastricus and Stylohyoideus have small insertions in front of these near the junction of the body with the cornu. To the medial border the hyothyroid membrane is attached, while the anterior half of the lateral border gives insertion to the Thyrohyoideus.

The Lesser Cornua or Ceratohyals (*cornua minora*).—The

lesser cornu are two small, conical eminences, attached by their bases to the angles of junction between the body and greater cornua. They are connected to the body of the bone

GENIOHYOIDEUS

FIG. 330.—Hyoid bone. Anterior surface. Enlarged.

by fibrous tissue, and occasionally to the greater cornua by distinct diarthrodial joints, which usually persist throughout life, but occasionally become ankylosed.

The lesser cornua are situated in the line of the transverse ridge on the body and appear to be morphological continuations of it (Parsons¹). The apex of each cornu gives attachment to the stylohyoid ligament;² the Chondroglossus rises from the medial side of the base.

Ossification.—The hyoid is ossified from six centres: two for the body, and one for each cornu. Ossification commences in the greater cornua toward the end of fetal life, in the body shortly afterward, and in the lesser cornua during the first or second year after birth.

Applied Anatomy.—The hyoid bone is occasionally fractured, generally from direct violence, as in hanging, forcible grasping of the throat in garroting or throttling, or by a blow. The fracture generally occurs about the junction of the greater cornu with the body of the bone, but sometimes takes place through the latter; since the muscles of the tongue have important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

THE EXTERIOR OF THE SKULL.

The skull as a whole may be viewed from different points, and the views so obtained are termed the *normæ* of the skull; thus, it may be examined from above (*norma verticalis*), from below (*norma basalis*), from the side (*norma lateralis*), from behind (*norma occipitalis*), or from the front (*norma frontalis*).

Norma Verticalis.—When viewed from above the outline presented varies greatly in different skulls; in some it is more or less oval, in others more nearly circular. The surface is traversed by three sutures, viz.: (1) the **coronal sutures**, nearly transverse in direction, between the frontal and parietals; (2) the **sagittal sutures**, medially placed, between the parietal bones, and deeply serrated in its anterior two-thirds; and (3) the upper part of the **lambdoidal suture**, between the parietals and the occipital. The point of junction of the sagittal and coronal suture is named the **bregma**, that of the sagittal and lambdoid sutures, the **lambda**; they indicate respectively the positions of the anterior and posterior fontanelles in the fetal skull. On either side of the sagittal suture are the **parietal eminence** and **parietal**

¹ See article on "The Topography and Morphology of the Human Hyoid Bone," by F. C. Parsons, *Journal of Anatomy and Physiology*, vol. xliii.

² These ligaments in many animals are distinct bones, and in man may undergo partial ossification.

foramen—the latter, however, is frequently absent on one or both sides. The skull is often somewhat flattened in the neighborhood of the parietal foramina, and the term **obelion** is applied to that point of the sagittal suture which is on a level with the foramina. In front is the **glabella**, and on its lateral aspects are the **superciliary arches**, and above these the **frontal eminences**. Immediately above the glabella may be seen the remains of the **frontal suture**; in a small percentage of skulls this suture persists and extends along the middle line to the bregma. Passing backward and upward from the zygomatic processes of the frontal bone are the **temporal lines**, which mark the upper limits of the temporal fossæ. The zygomatic arches may or may not be seen projecting beyond the anterior portions of these lines.

Norma Basalis (Fig. 331).—The inferior surface of the base of the skull, exclusive of the mandible, is bounded in front by the incisor teeth in the maxillæ; behind, by the superior nuchal lines of the occipital; and laterally by the alveolar arch, the lower border of the zygomatic bone, the zygomatic arch and an imaginary line extending from it to the mastoid process and extremity of the superior nuchal line of the occipital. It is formed by the palatine processes of the maxillæ and palatine bones, the vomer, the pterygoid processes, the under surfaces of the great wings, spinous processes, and part of the body of the sphenoid, the under surfaces of the squamæ and mastoid and petrous portions of the temporals, and the under surface of the occipital bone. The anterior part or hard palate projects below the level of the rest of the surface, and is bounded in front and laterally by the alveolar arch containing the sixteen teeth of the maxillæ. Immediately behind the incisor teeth is the **incisive foramen**. In this foramen are two lateral apertures, the openings of the **incisive canals** (*foramina of Stensen*) which transmit the anterior branches of the descending palatine vessels, and the nasopalatine nerves. Occasionally two additional canals are present in the incisive foramen; they are termed the **foramina of Scarpa** and are situated in the middle line; when present they transmit the nasopalatine nerves. The vault of the hard palate is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and traversed by a crucial suture formed by the junction of the four bones of which it is composed. In the young skull a suture may be seen extending on either side from the incisive foramen to the interval between the lateral incisor and canine teeth, and marking off the os incisivum or premaxillary bone. At either posterior angle of the hard palate is the **greater palatine foramen**, for the transmission of the descending palatine vessels and anterior palatine nerve; and running forward and medialward from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the **pyramidal process of the palatine bone**, perforated by one or more **lesser palatine foramina**, and marked by the commencement of a transverse ridge, for the attachment of the tendinous expansion of the Tensor veli palatini. Projecting backward from the centre of the posterior border of the hard palate is the **posterior nasal spine**, for the attachment of the Musculus uvulæ. Behind and above the hard palate are the **choanæ**, measuring about 2.5 cm. in their vertical and 1.25 cm. in their transverse diameters. They are separated from one another by the vomer, and each is bounded above by the body of the sphenoid, below by the horizontal part of the palatine bone, and laterally by the medial pterygoid plate of the sphenoid. At the superior border of the vomer may be seen the expanded alæ of this bone, receiving between them the rostrum of the sphenoid. Near the lateral margins of the alæ of the vomer, at the roots of the pterygoid processes, are the **pharyngeal canals**. The pterygoid process presents near its base the **pterygoid canal**, for the transmission of a nerve and artery. The medial pterygoid plate is long and narrow; on the lateral side of its base is the **scaphoid fossa**, for the origin of the Tensor veli palatini, and at its lower extremity the **hamulus**, around which the tendon of this muscle turns. The lateral pterygoid

plate is broad; its lateral surface forms the medial boundary of the infratemporal fossa, and affords attachment to the Pterygoideus externus.

Behind the nasal cavities is the basilar portion of the occipital bone, presenting near its centre the **pharyngeal tubercle** for the attachment of the fibrous raphe of the pharynx, with depressions on either side for the insertions of the Rectus capitis anterior and Longus capitis. At the base of the lateral pterygoid plate is the **foramen ovale**, for the transmission of the mandibular nerve, the accessory meningeal artery, and sometimes the lesser superficial petrosal nerve; behind this are the **foramen spinosum** which transmits the middle meningeal vessels, and the prominent **spina angularis** (*sphenoidal spine*), which gives attachment to the sphenomandibular ligament and the Tensor veli palatini. Lateral to the spina angularis is the **mandibular fossa**, divided into two parts by the **petrotympanic fissure**; the anterior portion, concave, smooth, bounded in front by the **articular tubercle**, serves for the articulation of the condyle of the mandible; the posterior portion, rough and bounded behind by the tympanic part of the temporal, is sometimes occupied by a part of the parotid gland. Emerging from between the laminae of the vaginal process of the tympanic part is the **styloid process**; and at the base of this process is the **stylomastoid foramen**, for the exit of the facial nerve, and entrance of the stylomastoid artery. Lateral to the stylomastoid foramen, between the tympanic part and the mastoid process, is the **tympanomastoid fissure**, for the auricular branch of the vagus. Upon the medial side of the mastoid process is the **mastoid notch** for the posterior belly of the Digastricus, and medial to the notch, the **occipital groove** for the occipital artery. At the base of the medial pterygoid plate is a large and somewhat triangular aperture, the **foramen lacerum**, bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and medially by the body of the sphenoid and basilar portion of the occipital bone; it presents in front the posterior orifice of the **pterygoid canal**; behind, the aperture of the **carotid canal**. The lower part of this opening is filled up in the recent state by a fibrocartilaginous plate, across the upper or cerebral surface of which the internal carotid artery passes. Lateral to this aperture is a groove, the **sulcus tubae auditivae**, between the petrous part of the temporal and the great wing of the sphenoid. This sulcus is directed lateralward and backward from the root of the medial pterygoid plate and lodges the cartilaginous part of the auditory tube; it is continuous behind with the canal in the temporal bone which forms the bony part of the same tube. At the bottom of this sulcus is a narrow cleft, the **petrosphenoidal fissure**, which is occupied, in the recent condition, by a plate of cartilage. Behind this fissure is the under surface of the petrous portion of the temporal bone, presenting, near its apex, the quadrilateral rough surface, part of which affords attachment to the Levator veli palatini; lateral to this surface is the orifice of the **carotid canal**, and medial to it, the depression leading to the **aquaeductus cochleae**, the former transmitting the internal carotid artery and the carotid plexus of the sympathetic, the latter serving for the passage of a vein from the cochlea. Behind the carotid canal is the **jugular foramen**, a large aperture, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and may be subdivided into three compartments. The anterior compartment transmits the inferior petrosal sinus; the intermediate, the glossopharyngeal, vagus, and accessory nerves; the posterior, the transverse sinus and some meningeal branches from the occipital and ascending pharyngeal arteries. On the ridge of bone dividing the carotid canal from the jugular foramen is the **inferior tympanic canaliculus** for the transmission of the tympanic branch of the glossopharyngeal nerve; and on the wall of the jugular foramen, near the root of the styloid process, is the **mastoid canaliculus** for the passage of the auricular branch of the vagus nerve. Extending forward from the jugular foramen to the foramen lacerum is the **petrooccipital fissure** occupied, in the recent state, by a plate of cartilage. Behind the basilar portion of the occipital bone is the **foramen magnum**, bounded laterally by the occipital

condyles, the medial sides of which are rough for the attachment of the alar ligaments. Lateral to each condyle is the **jugular process** which gives attachment to the Rectus capitis lateralis muscle and the lateral atlantooccipital ligament. The **foramen magnum** transmits the medulla oblongata and its membranes, the accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the ligaments connecting the occipital bone with the axis. The mid-points on the anterior and posterior margins of the foramen magnum are respectively termed the **basion** and the **opisthion**. In front of each condyle is the canal for the passage of the hypoglossal nerve and a meningeal artery. Behind each condyle is the **condyloid fossa**, perforated on one or both sides by the condyloid canal, for the transmission of a vein from the transverse sinus. Behind the foramen magnum is the **median nuchal line** ending above at the **external occipital protuberance**, while on either side are the **superior** and **inferior nuchal lines**; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles which are enumerated on pages 227 and 228.

FIG. 332.—Side view of the skull.

Norma Lateralis (Fig. 332).—When viewed from the side the skull is seen to consist of the cranium above and behind, and of the face below and in front. The cranium is somewhat ovoid in shape, but its contour varies in different cases and depends largely on the length and height of the skull and on the degree of prominence of the superciliary arches and frontal eminences. Entering into its formation are the frontal, the parietal, the occipital, the temporal, and the great wing of the sphenoid. These bones are joined to one another and to the zygomatic by the follow-

ing sutures: the **zygomaticotemporal** between the zygomatic process of the temporal and the temporal process of the zygomatic; the **zygomaticofrontal** uniting the zygomatic bone with the zygomatic process of the frontal; the sutures surrounding the great wing of the sphenoid, viz., the **sphenozygomatic** in front, the **sphenofrontal** and **sphenoparietal** above, and the **sphenosquamosal** behind. The sphenoparietal suture varies in length in different skulls, and is absent in those cases where the frontal articulates with the temporal squama. The point corresponding with the posterior end of the sphenoparietal suture is named the **pterion**; it is situated about 3 cm. behind, and a little above the level of the zygomatic process of the frontal bone.

The **squamosal suture** arches backward from the pterion and connects the temporal squama with the lower border of the parietal: this suture is continuous behind with the short, nearly horizontal **parietomastoid suture**, which unites the mastoid process of the temporal with the region of the mastoid angle of the parietal. Extending from above downward and forward across the cranium are the **coronal** and **lambdoidal sutures**; the former connects the parietals with the frontal, the latter, the parietals with the occipital. The lambdoidal suture is continuous below with the **occipitomastoid suture** between the occipital and the mastoid portion of the temporal. In or near the last suture is the **mastoid foramen**, for the transmission of an emissary vein. The point of meeting of the parietomastoid, occipitomastoid, and lambdoidal sutures is known as the **asterion**. Immediately above the orbital margin is the **superciliary arch**, and, at a higher level, the **frontal eminence**. Near the centre of the parietal bone is the **parietal eminence**. Posteriorly is the **external occipital protuberance**, from which the superior nuchal line may be followed forward to the mastoid process. Arching across the side of the cranium are the **temporal lines**, which mark the upper limit of the temporal fossa.

The Temporal Fossa (*fossa temporalis*).—The temporal fossa is bounded above and behind by the temporal lines, which extend from the zygomatic process of the frontal bone upward and backward across the frontal and parietal bones, and then curve downward and forward to become continuous with the supramastoid crest and the posterior root of the zygomatic arch. The point where the upper temporal line cuts the coronal suture is named the **stephanion**. The temporal fossa is bounded in *front* by the frontal and zygomatic bones, and opening on the back of the latter is the **zygomaticotemporal foramen**. *Laterally* the fossa is limited by the zygomatic arch, formed by the zygomatic and temporal bones; *below*, it is separated from the infratemporal fossa by the **infratemporal crest** on the great wing of the sphenoid, and by a ridge, continuous with this crest, which is carried backward across the temporal squama to the anterior root of the zygomatic process. In front and below, the fossa communicates with the orbital cavity through the **inferior orbital** or **sphenomaxillary fissure**. The floor of the fossa is deeply concave in front and convex behind, and is formed by the zygomatic, frontal, parietal, sphenoid, and temporal bones. It is traversed by vascular furrows; one, usually well-marked, runs upward above and in front of the external acoustic meatus, and lodges the middle temporal artery. Two others, frequently indistinct, may be observed on the anterior part of the floor, and are for the anterior and posterior deep temporal arteries. The temporal fossa contains the Temporalis muscle and its vessels and nerves, together with the zygomaticotemporal nerve.

The **zygomatic arch** is formed by the zygomatic process of the temporal and the temporal process of the zygomatic, the two being united by an oblique suture; the tendon of the Temporalis passes medial to the arch to gain insertion into the coronoid process of the mandible. The zygomatic process of the temporal arises by two roots, an anterior, directed inward in front of the mandibular fossa, where it expands to form the articular tubercle, and a posterior, which runs backward above the external acoustic meatus and is continuous with the supramastoid

crest. The upper border of the arch gives attachment to the temporal fascia; the lower border and medial surface give origin to the Masseter.

Below the posterior root of the zygomatic arch is the elliptical orifice of the **external acoustic meatus**, bounded in front, below, and behind by the tympanic part of the temporal bone; to its outer margin the cartilaginous segment of the external acoustic meatus is attached. The small triangular area between the posterior root of the zygomatic arch and the postero-superior part of the orifice is termed the **suprameatal triangle**, on the anterior border of which a small spinous process, the **suprameatal spine**, is sometimes seen. Between the tympanic part and the articular tubercle is the **mandibular fossa**, divided into two parts by the petrotympanic fissure. The anterior and larger part of the fossa articulates with the condyle of the mandible and is limited behind by the external acoustic meatus: the posterior part sometimes lodges a portion of the parotid gland. The styloid process extends downward and forward for a variable distance from the lower part of the tympanic part, and gives attachment to the Styloglossus, Stylohyoideus, and Stylopharyngeus, and to the stylohyoid and stylomandibular ligaments. Projecting downward behind the external acoustic meatus is the mastoid process, to the outer surface of which the Sternocleidomastoideus, Splenius capitis, and Longissimus capitis are attached.

acoustic meatus
of temporal

Pterygoid hamulus

FIG. 333 —Left infratemporal fossa.

The Infratemporal Fossa (*fossa infratemporalis*; *zygomatic fossa*) (Fig. 333).—The infratemporal fossa is an irregularly shaped cavity, situated below and medial to the **zygomatic arch**. It is bounded, in *front*, by the infratemporal surface of the maxilla and the ridge which descends from its zygomatic process; *behind*, by the articular tubercle of the temporal and the spina angularis of the sphenoid; *above*, by the great wing of the sphenoid below the infratemporal crest, and by the under surface of

the temporal squama; *below*, by the alveolar border of the maxilla; *medially*, by the lateral pterygoid plate. It contains the lower part of the Temporalis, the Pterygoidei internus and externus, the internal maxillary vessels, and the mandibular and maxillary nerves. The **foramen ovale** and **foramen spinosum** open on its roof, and the **alveolar canals** on its anterior wall. At its upper and medial part are two fissures, which together form a T-shaped fissure, the horizontal limb being named the inferior orbital, and the vertical one the pterygomaxillary.

The **inferior orbital fissure** (*fissura orbitalis inferior; sphenomaxillary fissure*), horizontal in direction, opens into the lateral and back part of the orbit. It is bounded *above* by the lower border of the orbital surface of the great wing of the sphenoid; *below*, by the lateral border of the orbital surface of the maxilla and the orbital process of the palatine bone; *laterally*, by a small part of the zygomatic bone;¹ *medially*, it joins at right angles with the pterygomaxillary fissure. Through the inferior orbital fissure the orbit communicates with the temporal, infratemporal, and pterygopalatine fossæ; the fissure transmits the maxillary nerve and its zygomatic branch, the infraorbital vessels, the ascending branches from the sphenopalatine ganglion, and a vein which connects the inferior ophthalmic vein with the pterygoid venous plexus.

The **pterygomaxillary fissure** is vertical, and descends at right angles from the medial end of the preceding; it is a triangular interval, formed by the divergence of the maxilla from the pterygoid process of the sphenoid. It connects the infratemporal with the pterygopalatine fossa, and transmits the terminal part of the internal maxillary artery.

The **Pterygopalatine Fossa** (*fossa pterygopalatina; sphenomaxillary fossa*).—The pterygopalatine fossa is a small, triangular space at the angle of junction of the inferior orbital and pterygomaxillary fissures, and placed beneath the apex of the orbit. It is bounded *above* by the under surface of the body of the sphenoid and by the orbital process of the palatine bone; in *front*, by the infratemporal surface of the maxilla; *behind*, by the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoid; *medially*, by the vertical part of the palatine bone with its orbital and sphenoidal processes. This fossa communicates with the orbit by the inferior orbital fissure, with the nasal cavity by the sphenopalatine foramen, and with the infratemporal fossa by the pterygomaxillary fissure. Five foramina open into it. Of these, three are on the posterior wall, viz., the **foramen rotundum**, the **pterygoid canal**, and the **pharyngeal canal**, in this order downward and medialward. On the medial wall is the **sphenopalatine foramen**, and below is the superior orifice of the **pterygopalatine canal**. The fossa contains the maxillary nerve, the sphenopalatine ganglion, and the terminal part of the internal maxillary artery.

Norma Occipitalis.—When viewed from behind the cranium presents a more or less circular outline. In the middle line is the posterior part of the **sagittal suture** connecting the parietal bones; extending downward and lateralward from the hinder end of the sagittal suture is the deeply serrated **lambdoidal suture** joining the parietals to the occipital and continuous below with the **parietomastoid** and **occipitomastoid sutures**; it frequently contains one or more sutural bones. Near the middle of the occipital squama is the **external occipital protuberance** or **inion**, and extending lateralward from it on either side is the superior nuchal line, and above this the faintly marked highest nuchal line. The part of the squama above the inion and highest lines is named the **planum occipitale**, and is covered by the Occipitalis muscle; the part below is termed the **planum nuchale**, and is divided by the median nuchal line which runs downward and forward from the inion to the foramen magnum; this ridge gives attachment to the ligamentum nuchae. The

¹ Occasionally the maxilla and the sphenoid articulate with each other at the anterior extremity of this fissure; the zygomatic is then excluded from it.

muscles attached to the *planum nuchale* are enumerated on p. 227. Below and in front are the mastoid processes, convex laterally and grooved medially by the mastoid notches. In or near the occipitomastoid suture is the **mastoid foramen** for the passage of the mastoid emissary vein.

FIG. 334.—The skull from the front.

Norma Frontalis (Fig. 334).—When viewed from the front the skull exhibits a somewhat oval outline, limited *above* by the frontal bone, *below* by the body of the mandible, and *laterally* by the zygomatic bones and the mandibular rami. The upper part, formed by the frontal squama, is smooth and convex. The lower part, made up of the bones of the face, is irregular; it is excavated laterally by the orbital cavities, and presents in the middle line the **anterior nasal aperture** leading to the nasal cavities, and below this the transverse slit between the upper and lower dental arcades. *Above*, the **frontal eminences** stand out more or less prominently, and beneath these are the **superciliary arches**, joined to one another in the middle by the **glabella**. On and above the glabella a trace of the **frontal suture** sometimes persists; beneath it is the frontonasal suture, the mid-point of which is termed the **nasion**. Behind and below the frontonasal suture the frontal articulates with the frontal process of the maxilla and with the lacrimal. Arching transversely below

the superciliary arches is the upper part of the margin of the orbit, thin and prominent in its lateral two-thirds, rounded in its medial third, and presenting, at the junction of these two portions, the **supraorbital notch or foramen** for the supra-orbital nerve and vessels. The supraorbital margin ends laterally in the zygomatic process which articulates with the zygomatic bone, and from it the temporal line extends upward and backward. Below the frontonasal suture is the bridge of the nose, convex from side to side, concavo-convex from above downward, and formed by the two nasal bones supported in the middle line by the perpendicular plate of the ethmoid, and laterally by the frontal processes of the maxillæ which are prolonged upward between the nasal and lacrimal bones and form the lower and medial part of the circumference of each orbit. Below the nasal bones and between the maxillæ is the anterior aperture of the nose, pyriform in shape, with the narrow end directed upward. Laterally this opening is bounded by sharp margins, to which the lateral and alar cartilages of the nose are attached; *below*, the margins are thicker and curve medialward and forward to end in the **anterior nasal spine**. On looking into the nasal cavity, the bony septum which separates the nasal cavities presents, in front, a large triangular deficiency; this, in the recent state, is filled up by the cartilage of the nasal septum; on the lateral wall of each nasal cavity the anterior part of the inferior nasal concha is visible. Below and lateral to the anterior nasal aperture are the anterior surfaces of the maxillæ, each perforated, near the lower margin of the orbit, by the **infraorbital foramen** for the passage of the infraorbital nerve and vessels. Below and medial to this foramen is the canine eminence separating the incisor from the canine fossa. Beneath these fossæ are the alveolar processes of the maxillæ containing the upper teeth, which overlap the teeth of the mandible in front. The zygomatic bone on either side forms the prominence of the cheek, the lower and lateral portion of the orbital cavity, and the anterior part of the zygomatic arch. It articulates medially with the maxilla, behind with the zygomatic process of the temporal, and above with the great wing of the sphenoid and the zygomatic process of the frontal; it is perforated by the **zygomaticofacial foramen** for the passage of the zygomaticofacial nerve. On the body of the mandible is a median ridge, indicating the position of the symphysis; this ridge divides below to enclose the mental protuberance, the lateral angles of which constitute the mental tubercles. Below the incisor teeth is the **incisive fossa**, and beneath the second premolar tooth the **mental foramen** which transmits the mental nerve and vessels. The oblique line runs upward from the mental tubercle and is continuous behind with the anterior border of the ramus. The posterior border of the ramus runs downward and forward from the condyle to the angle, which is frequently more or less everted.

The Orbits (*orbitæ*) (Fig. 334).—The orbits are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forward and lateralward, and their apices backward and medialward, so that their long axes, if continued backward, would meet over the body of the sphenoid. Each presents for examination a **roof**, a **floor**, a **medial** and a **lateral wall**, a **base**, and an **apex**.

The **roof** is concave, directed downward, and slightly forward, and formed in *front* by the orbital plate of the frontal; *behind* by the small wing of the sphenoid. It presents *medially* the **trochlear fovea** for the attachment of the cartilaginous pulley of the Obliquus oculi superior; *laterally*, the **lacrimal fossa** for the lacrimal gland; and *posteriorly*, the suture between the frontal bone and the small wing of the sphenoid.

The **floor** is directed upward and lateralward, and is of less extent than the roof; it is formed chiefly by the orbital surface of the maxilla; in *front* and *laterally*, by the orbital process of the zygomatic bone, and *behind* and *medially*, to a small extent, by the orbital process of the palatine. At its medial angle is the upper

opening of the nasolacrimal canal, immediately to the lateral side of which is a depression for the origin of the *Obliquus oculi inferior*. On its lateral part is the suture between the maxilla and zygomatic bone, and at its posterior part that between the maxilla and the orbital process of the palatine. Running forward near the middle of the floor is the **infraorbital groove**, ending in front in the infra-orbital canal and transmitting the infraorbital nerve and vessels.

The **medial wall** (Fig. 335) is nearly vertical, and is formed from before backward by the frontal process of the maxilla, the lacrimal, the lamina papyracea of the ethmoid, and a small part of the body of the sphenoid in front of the optic foramen. Sometimes the sphenoidal concha forms a small part of this wall (see page 250). It exhibits three vertical sutures, viz., the lacrimomaxillary, lacrimo-ethmoidal, and sphenoeethmoidal. In front is seen the **lacrimal groove**, which lodges the lacrimal sac, and behind the groove is the **posterior lacrimal crest**, from which

FIG. 335.—Medial wall of left orbit

the lacrimal part of the *Orbicularis oculi* arises. At the junction of the medial wall and the roof are the frontomaxillary, frontolacrimal, frontoethmoidal, and sphenofrontal sutures. The point of junction of the anterior border of the lacrimal with the frontal is named the **dacryon**. In the frontoethmoidal suture are the **anterior and posterior ethmoidal foramina**, the former transmitting the nasociliary nerve and anterior ethmoidal vessels, the latter the posterior ethmoidal nerve and vessels.

The **lateral wall**, directed medialward and forward, is formed by the orbital process of the zygomatic and the orbital surface of the great wing of the sphenoid; these are united by the sphenozygomatic suture which terminates below at the front end of the inferior orbital fissure. On the orbital process of the zygomatic bone are the orbital tubercle (Whitnall) and the orifices of one or two canals which transmit the branches of the zygomatic nerve. Between the roof and the lateral

wall, near the apex of the orbit, is the **superior orbital fissure**. Through this fissure the oculomotor, the trochlear, the ophthalmic division of the trigeminal, and the abducent nerves enter the orbital cavity, also some filaments from the cavernous plexus of the sympathetic and the orbital branches of the middle meningeal artery. Passing backward through the fissure are the ophthalmic vein and the recurrent branch from the lacrimal artery to the dura mater. The lateral wall and the floor are separated posteriorly by the **inferior orbital fissure** which transmits the maxillary nerve and its zygomatic branch, the infraorbital vessels, and the ascending branches from the sphenopalatine ganglion.

The **base** of the orbit, quadrilateral in shape, is formed *above* by the supra-orbital arch of the frontal bone, in which is the **supraorbital notch** or **foramen** for the passage of the supraorbital vessels and nerve; *below* by the zygomatic bone and maxilla, united by the zygomaticomaxillary suture; laterally by the zygomatic bone and the zygomatic process of the frontal joined by the zygomaticofrontal suture; medially by the frontal bone and the frontal process of the maxilla united by the frontomaxillary suture.

The **apex**, situated at the back of the orbit, corresponds to the optic foramen¹ a short, cylindrical canal, which transmits the optic nerve and ophthalmic artery.

It will thus be seen that there are nine openings communicating with each orbit, viz., the optic foramen, superior and inferior orbital fissures, supraorbital foramen, infraorbital canal, anterior and posterior ethmoidal foramina, zygomatic foramen, and the canal for the nasolacrimal duct.

THE INTERIOR OF THE SKULL.

In order to study the interior of the skull the skull-cap should be removed by a saw-cut carried around the cranium about the level of the frontal eminences and the upper limits of the squamosal sutures, cutting the occipital bone about 2.5 cm. above the external protuberance.

Inner Surface of the Skull-cap.—The inner surface of the skull-cap is concave and presents depressions for the convolutions of the cerebrum, together with numerous furrows for the lodgement of branches of the meningeal vessels. Along the middle line is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind; it lodges the superior sagittal sinus, and its margins afford attachment to the falx cerebri. On either side of it are several depressions for the arachnoid granulations, and at its back part, the openings of the **parietal foramina** when these are present. It is crossed, in front, by the **coronal suture**, and behind by the **lambdoidal**, while the **sagittal** lies in the medial plane between the parietal bones.

Upper Surface of the Base of the Skull (Fig. 336).—The upper surface of the base of the skull or floor of the cranial cavity presents three fossæ, called the **anterior**, **middle**, and **posterior cranial fossæ**.

Anterior Fossa (*fossa cranii anterior*).—The floor of the anterior fossa is formed by the orbital plates of the frontal, the cribriform plate of the ethmoid, and the small wings and front part of the body of the sphenoid; it is limited behind by the posterior borders of the small wings of the sphenoid and by the anterior margin of the chiasmatic groove. It is traversed by the **frontoethmoidal**, **sphenoethmoidal**, and **sphenofrontal sutures**. Its lateral portions roof in the orbital cavities and support the frontal lobes of the cerebrum; they are convex and marked by depressions for the brain convolutions, and grooves for branches of the meningeal vessels.

¹ Some anatomists describe the apex of the orbit as corresponding with the medial end of the superior orbital fissure. It seems better, however, to adopt the statement in the text, since the ocular muscles take origin around the optic foramen, and diverge from it to the bulb of the eye.

The central portion corresponds with the roof of the nasal cavity, and is markedly depressed on either side of the crista galli. It presents, in and near the median

line, from before backward, the commencement of the **frontal crest** for the attachment of the falx cerebri; the **foramen cecum**, between the frontal bone and the crista galli of the ethmoid, which usually transmits a small vein from the nasal cavity

to the superior sagittal sinus; behind the foramen cecum, the **crista galli**, the free margin of which affords attachment to the falx cerebri; on either side of the crista galli, the **olfactory groove** formed by the cribriform plate, which supports the olfactory bulb and presents foramina for the transmission of the olfactory nerves, and in front a slit-like opening for the nasociliary nerve. Lateral to either olfactory groove are the internal openings of the **anterior** and **posterior ethmoidal foramina**; the anterior, situated about the middle of the lateral margin of the olfactory groove, transmits the anterior ethmoidal vessels and the nasociliary nerve; the nerve runs in a groove along the lateral edge of the cribriform plate to the slit-like opening above mentioned; the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels and nerve. Farther back in the middle line is the **ethmoidal spine**, bounded behind by a slight elevation separating two shallow longitudinal grooves which support the olfactory lobes. Behind this is the anterior margin of the chiasmatic groove, running lateralward on either side to the upper margin of the optic foramen.

The Middle Fossa (*fossa cranii media*).—The middle fossa, deeper than the preceding, is narrow in the middle, and wide at the sides of the skull. It is bounded in *front* by the posterior margins of the small wings of the sphenoid, the anterior clinoid processes, and the ridge forming the anterior margin of the chiasmatic groove; *behind*, by the superior angles of the petrous portions of the temporals and the dorsum sellae; *laterally* by the temporal squamæ, sphenoidal angles of the parietals, and great wings of the sphenoid. It is traversed by the **squamosal**, **sphenoparietal**, **sphenosquamosal**, and **sphenopetrosal sutures**.

The middle part of the fossa presents, in *front*, the **chiasmatic groove** and **tuberculum sellae**; the chiasmatic groove ends on either side at the **optic foramen**, which transmits the optic nerve and ophthalmic artery to the orbital cavity. Behind the optic foramen the **anterior clinoid process** is directed backward and medialward and gives attachment to the tentorium cerebelli. Behind the tuberculum sellae is a deep depression, the **sella turcica**, containing the **fossa hypophyseos**, which lodges the hypophysis, and presents on its anterior wall the **middle clinoid processes**. The sella turcica is bounded posteriorly by a quadrilateral plate of bone, the **dorsum sellae**, the upper angles of which are surmounted by the **posterior clinoid processes**: these afford attachment to the tentorium cerebelli, and below each is a notch for the abducent nerve. On either side of the sella turcica is the **carotid groove**, which is broad, shallow, and curved somewhat like the italic letter *f*. It begins behind at the foramen lacerum, and ends on the medial side of the anterior clinoid process, where it is sometimes converted into a foramen (*carotico-clinoid*) by the union of the anterior with the middle clinoid process; posteriorly, it is bounded laterally by the **lingula**. This groove lodges the cavernous sinus and the internal carotid artery, the latter being surrounded by a plexus of sympathetic nerves.

The lateral parts of the middle fossa are of considerable depth, and support the temporal lobes of the brain. They are marked by depressions for the brain convolutions and traversed by furrows for the anterior and posterior branches of the middle meningeal vessels. These furrows begin near the foramen spinosum, and the anterior runs forward and upward to the sphenoidal angle of the parietal, where it is sometimes converted into a bony canal; the posterior runs lateralward and backward across the temporal squama and passes on to the parietal near the middle of its lower border. The following apertures are also to be seen. In front is the **superior orbital fissure**, bounded above by the small wing, below, by the great wing, and medially, by the body of the sphenoid; it is usually completed laterally by the orbital plate of the frontal bone. It transmits to the orbital cavity the oculomotor, the trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, some filaments from the cavernous plexus of the

sympathetic, and the orbital branch of the middle meningeal artery; and from the orbital cavity a recurrent branch from the lacrimal artery to the dura mater, and the ophthalmic veins. Behind the medial end of the superior orbital fissure is the **foramen rotundum**, for the passage of the maxillary nerve. Behind and lateral to the foramen rotundum is the **foramen ovale**, which transmits the mandibular nerve, the accessory meningeal artery, and the lesser superficial petrosal nerve.¹ Medial to the foramen ovale is the **foramen Vesalii**, which varies in size in different individuals, and is often absent; when present, it opens below at the lateral side of the scaphoid fossa, and transmits a small vein. Lateral to the foramen ovale is the **foramen spinosum**, for the passage of the middle meningeal vessels, and a recurrent branch from the mandibular nerve. Medial to the foramen ovale is the **foramen lacerum**; in the recent state the lower part of this aperture is filled up by a layer of fibrocartilage, while its upper and inner parts transmit the internal carotid artery surrounded by a plexus of sympathetic nerves. The nerve of the pterygoid canal and a meningeal branch from the ascending pharyngeal artery pierce the layer of fibrocartilage. On the anterior surface of the petrous portion of the temporal bone are seen the eminence caused by the projection of the superior semicircular canal; in front of and a little lateral to this a depression corresponding to the roof of the tympanic cavity; the groove leading to the **hiatus of the facial canal**, for the transmission of the greater superficial petrosal nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the lesser superficial petrosal nerve; and, near the apex of the bone, the depression for the semilunar ganglion and the orifice of the carotid canal.

The Posterior Fossa (*fossa cranii posterior*).—The posterior fossa is the largest and deepest of the three. It is formed by the dorsum sellae and clivus of the sphenoid, the occipital, the petrous and mastoid portions of the temporals, and the mastoid angles of the parietal bones; it is crossed by the **occipitomastoid** and the **parietomastoid sutures**, and lodges the cerebellum, pons, and medulla oblongata. It is separated from the middle fossa in and near the median line by the dorsum sellae of the sphenoid and on either side by the superior angle of the petrous portion of the temporal bone. This angle gives attachment to the tentorium cerebelli, is grooved for the superior petrosal sinus, and presents at its medial end a notch upon which the trigeminal nerve rests. The fossa is limited behind by the grooves for the transverse sinuses. In its centre is the **foramen magnum**, on either side of which is a rough tubercle for the attachment of the alar ligaments; a little above this tubercle is the canal, which transmits the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum the basilar portion of the occipital and the posterior part of the body of the sphenoid form a grooved surface which supports the medulla oblongata and pons; in the young skull these bones are joined by a synchondrosis. This grooved surface is separated on either side from the petrous portion of the temporal by the **petro-occipital fissure**, which is occupied in the recent state by a plate of cartilage; the fissure is continuous behind with the jugular foramen, and its margins are grooved for the inferior petrosal sinus. The **jugular foramen** is situated between the lateral part of the occipital and the petrous part of the temporal. The anterior portion of this foramen transmits the inferior petrosal sinus; the posterior portion, the transverse sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and the intermediate portion, the glossopharyngeal, vagus, and accessory nerves. Above the jugular foramen is the **internal acoustic meatus**, for the facial and acoustic nerves and internal auditory artery; behind and lateral to this is the slit-like opening leading into the aquaeductus vestibuli, which lodges the ductus endolymphaticus; while between these, and near the superior angle of

¹ See footnote, page 248.

the petrous portion, is a small triangular depression, the remains of the fossa sub-arcuata, which lodges a process of the dura mater and occasionally transmits a small vein. Behind the foramen magnum are the **inferior occipital fossæ**, which support the hemispheres of the cerebellum, separated from one another by the **internal occipital crest**, which serves for the attachment of the falx cerebelli, and lodges the occipital sinus. The posterior fossæ are surmounted by the deep grooves for the **transverse sinuses**. Each of these channels, in its passage to the jugular foramen, grooves the occipital; the mastoid angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and ends at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal, the orifice of the **mastoid foramen** may be seen; and, just previous to its termination, the **condyloid canal** opens into it; neither opening is constant.

FIG. 337.—Medial wall of left nasal fossa.

The Nasal Cavity (*cavum nasi; nasal fossa*).—The nasal cavities are two irregular spaces, situated one on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They open on the face through the pear-shaped **anterior nasal aperture**, and their posterior openings or **choanæ** communicate, in the recent state, with the nasal part of the pharynx. They are much narrower above than below, and in the middle than at their anterior or posterior openings: their depth, which is considerable, is greatest in the middle. They communicate with the frontal, ethmoidal, sphenoidal, and maxillary sinuses. Each cavity is bounded by a **roof**, a **floor**, a **medial** and a **lateral wall**.

The **roof** (Figs. 337, 338) is horizontal in its central part, but slopes downward in front and behind; it is formed in *front* by the nasal bone and the spine of the frontal; in the *middle*, by the cribriform plate of the ethmoid; and *behind*, by the body of the sphenoid, the sphenoidal concha, the ala of the vomer and the sphenoidal process of the palatine bone. In the cribriform plate of the ethmoid

are the foramina for the olfactory nerves, and on the posterior part of the roof is the opening into the sphenoidal sinus.

The **floor** is flattened from before backward and concave from side to side. It is formed by the palatine process of the maxilla and the horizontal part of the palatine bone; near its anterior end is the opening of the incisive canal.

The **medial wall** (*septum nasi*) (Fig. 337), is frequently deflected to one or other side, more often to the left than to the right. It is formed, in *front*, by the crest of the nasal bones and frontal spine; in the *middle*, by the perpendicular plate of the ethmoid; *behind*, by the vomer and the rostrum of the sphenoid; *below*, by the crest of the maxillæ and palatine bones. It presents, in front, a large, triangular notch, which receives the cartilage of the septum; and behind, the free edge of the vomer. Its surface is marked by numerous furrows for vessels and nerves and by the grooves for the nasopalatine nerve, and is traversed by sutures connecting the bones of which it is formed.

FIG. 338.—Roof, floor, and lateral wall of left nasal cavity

The **lateral wall** (Fig. 338) is formed, in front, by the frontal process of the maxilla and by the lacrimal bone; in the middle, by the ethmoid, maxilla, and inferior nasal concha; behind, by the vertical plate of the palatine bone, and the medial pterygoid plate of the sphenoid. On this wall are three irregular antero-posterior passages, termed the superior, middle, and inferior meatuses of the nose. The **superior meatus**, the smallest of the three, occupies the middle third of the lateral wall. It lies between the superior and middle nasal conchæ; the **spheno-palatine foramen** opens into it behind, and the **posterior ethmoidal cells** in front. The sphenoidal sinus opens into a recess, the **sphenoethmoidal recess**, which is placed above and behind the superior concha. The **middle meatus** is situated between the middle and inferior conchæ, and extends from the anterior to the posterior end of the latter. The lateral wall of this meatus can be satisfactorily studied only after the removal of the middle concha. On it is a curved fissure, the **hiatus semilunaris**,

limited below by the edge of the uncinat process of the ethmoid and above by an elevation named the **bullæ ethmoidalis**; the middle ethmoidal cells are contained within this bulla and open on or near to it. Through the hiatus semilunaris the meatus communicates with a curved passage termed the **infundibulum**, which communicates in front with the anterior ethmoidal cells and in rather more than fifty per cent. of skulls is continued upward as the **frontonasal duct** into the frontal air-sinus; when this continuity fails, the frontonasal duct opens directly into the anterior part of the meatus. Below the bulla ethmoidalis and hidden by the uncinat process of the ethmoid is the opening of the maxillary sinus (**ostium maxillare**); an accessory opening is frequently present above the posterior part of the inferior nasal concha. The **inferior meatus**, the largest of the three, is the space between the inferior concha and the floor of the nasal cavity. It extends almost the entire length of the lateral wall of the nose, is broader in front than behind, and presents anteriorly the lower orifice of the **nasolacrimal canal**.

The **Anterior Nasal Aperture** (Fig. 334) is a heart-shaped or pyriform opening, whose long axis is vertical, and narrow end upward; in the recent state it is much contracted by the lateral and alar cartilages of the nose. It is bounded *above* by the inferior borders of the nasal bones; *laterally* by the thin, sharp margins which separate the anterior from the nasal surfaces of the maxillæ; and *below* by the same borders, where they curve medialward to join each other at the anterior nasal spine.

The **choanæ** are each bounded *above* by the under surface of the body of the sphenoid and ala of the vomer; *below*, by the posterior border of the horizontal part of the palatine bone; *laterally*, by the medial pterygoid plate; they are separated from each other by the posterior border of the vomer.

DIFFERENCES IN THE SKULL DUE TO AGE.

At birth the skull is large in proportion to the other parts of the skeleton, but its facial portion is small, and equals only about one-eighth of the bulk of the cranium as compared with one-half in the adult. The frontal and parietal eminences are prominent, and the greatest width of the skull is at the level of the latter; on the other hand, the glabella, superciliary arches, and mastoid processes are not developed. Ossification of the skull bones is not completed, and many of them, *e. g.*, the occipital, temporals, sphenoid, frontal, and mandible, consist of more than one piece. Unossified membranous intervals, termed **fontanelles**, are seen at the angles of the parietal bones; these fontanelles are six in number: two, an anterior and a posterior, are situated in the middle line, and two, an antero-lateral and a postero-lateral, on either side.

FIG. 339.—Skull at birth showing anterior and posterior fontanelles.

FIG. 340.—The lateral fontanelles.

The **anterior or bregmatic fontanelle** (Fig. 339) is the largest, and is placed at the junction of the sagittal, coronal, and frontal sutures; it is lozenge-shaped, and measures about 4 cm. in its antero-posterior and 2.5 cm. in its transverse diameter. The **posterior fontanelle** is triangular

in form and is situated at the junction of the sagittal and lambdoidal sutures. The *lateral fontanelles* (Fig. 340) are small, irregular in shape, and correspond respectively with the sphenoidal and mastoid angles of the parietal bones. An additional fontanelle is sometimes seen in the sagittal suture at the region of the obelion. The fontanelles are usually closed by the growth and extension of the bones which surround them, but sometimes they are the sites of separate ossific centres which develop into sutural bones. The posterior and lateral fontanelles are obliterated within a month or two after birth, but the anterior is not completely closed until about the middle of the second year.

The smallness of the face at birth is mainly accounted for by the rudimentary condition of the maxillæ and mandible, the non-eruption of the teeth, and the small size of the maxillary air sinuses and nasal cavities. At birth the nasal cavities lie almost entirely between the orbits, and the lower border of the anterior nasal aperture is only a little below the level of the orbital floor. With the eruption of the deciduous teeth there is an enlargement of the face and jaws, and these changes are still more marked after the second dentition.

The skull grows rapidly from birth to the seventh year, by which time the foramen magnum and petrous parts of the temporals have reached their full size and the orbital cavities are only a little smaller than those of the adult. Growth is slow from the seventh year until the approach of puberty, when a second period of activity occurs: this results in an increase in all directions, but it is especially marked in the frontal and facial regions, where it is associated with the development of the air sinuses.

Obliteration of the sutures of the vault of the skull takes place as age advances. This process may commence between the ages of thirty and forty, and is first seen on the inner surface, and some ten years later on the outer surface of the skull. The dates given are, however, only approximate, as it is impossible to state with anything like accuracy the time at which the sutures are closed. Obliteration usually occurs first in the posterior part of the sagittal suture, next in the coronal, and then in the lambdoidal.

In old age the skull generally becomes thinner and lighter, but in a small proportion of cases it increases in thickness and weight, owing to an hypertrophy of the inner table. The most striking feature of the old skull is the diminution in the size of the maxillæ and mandible consequent on the loss of the teeth and the absorption of the alveolar processes. This is associated with a marked reduction in the vertical measurement of the face and with an alteration in the angles of the mandible.

SEXUAL DIFFERENCES IN THE SKULL.

Until the age of puberty there is little difference between the skull of the female and that of the male. The skull of an adult female is, as a rule, lighter and smaller, and its cranial capacity about 10 per cent. less, than that of the male. Its walls are thinner and its muscular ridges less strongly marked; the glabella, superciliary arches, and mastoid processes are less prominent, and the corresponding air sinuses are small or rudimentary. The upper margin of the orbit is sharp, the forehead vertical, the frontal and parietal eminences prominent, and the vault somewhat flattened. The contour of the face is more rounded, the facial bones are smoother, and the maxillæ and mandible and their contained teeth smaller. From what has been said it will be seen that more of the infantile characteristics are retained in the skull of the adult female than in that of the adult male. A well-marked male or female skull can easily be recognized as such, but in some cases the respective characteristics are so indistinct that the determination of the sex may be difficult or impossible.

CRANIOLOGY.

Skulls vary in size and shape, and the term *craniology* is applied to the study of these variations. The capacity of the cranial cavity constitutes a good index of the size of the brain which it contained, and is most conveniently arrived at by filling the cavity with shot and measuring the contents in a graduated vessel. Skulls may be classified according to their capacities as follows:

1. *Microcephalic*, with a capacity of less than 1350 c.cm.—*e. g.*, those of native Australians and Andaman Islanders.
2. *Mesocephalic*, with a capacity of from 1350 c.cm. to 1450 c.cm.—*e. g.*, those of African negroes and Chinese.
3. *Megacephalic*, with a capacity of over 1450 c.cm.—*e. g.*, those of Europeans, Japanese, and Eskimos.

In comparing the shape of one skull with that of another it is necessary to adopt some definite position in which the skulls should be placed during the process of examination. They should be so placed that a line carried through the lower margin of the orbit and upper margin of the external acoustic meatus is in the horizontal plane. The normæ of one skull can then be compared with those of another, and the differences in contour and surface form noted. Further,

it is necessary that the various linear measurements used to determine the shape of the skull should be made between definite and easily localized points on its surface. The principal points may be divided into two groups: (1) those in the median plane, and (2) those on either side of it.

The Points in the Median Plane are the:

Mental Point. The most prominent point of the chin.

Alveolar Point or *Prosthion.* The central point of the anterior margin of the upper alveolar arch.

Subnasal Point. The middle of the lower border of the anterior nasal aperture, at the base of the anterior nasal spine.

Nasion. The central point of the frontonasal suture.

Glabella. The point in the middle line at the level of the superciliary arches.

Ophryon. The point in the middle line of the forehead at the level where the temporal lines most nearly approach each other.

Bregma. The meeting point of the coronal and sagittal sutures.

Obelion. A point in the sagittal suture on a level with the parietal foramina.

Lambda. The point of junction of the sagittal and lambdoidal sutures.

Occipital Point. The point in the middle line of the occipital bone farthest from the glabella.

Inion. The external occipital protuberance.

Opisthion. The mid-point of the posterior margin of the foramen magnum.

Basion. The mid-point of the anterior margin of the foramen magnum.

The Points on Either Side of the Median Plane are the:

Gonion. The outer margin of the angle of the mandible.

Dacryon. The point of union of the antero-superior angle of the lacrimal with the frontal bone and the frontal process of the maxilla.

Stephanion. The point where the temporal line intersects the coronal suture.

Pterion. The point where the great wing of the sphenoid joins the sphenoidal angle of the parietal.

Auricular Point. The centre of the orifice of the external acoustic meatus.

Asterion. The point of meeting of the lambdoidal, mastooccipital, and mastoparietal sutures.

The *horizontal circumference* of the cranium is measured in a plane passing through the glabella (Turner) or the ophryon (Flower) in front, and the occipital point behind; it averages about 50 cm. in the female and 52.5 cm. in the male.

The *occipitofrontal* or *longitudinal arc* is measured from the nasion over the middle line of the vertex to the opisthion: while the *basinasal length* is the distance between the basion and the nasion. These two measurements, plus the antero-posterior diameter of the foramen magnum, represent the *vertical circumference* of the cranium.

The *length* is measured from the glabella to the occipital point, while the *breadth* or greatest transverse diameter is usually found near the external acoustic meatus. The proportion of breadth to length $\frac{(\text{breadth} \times 100)}{\text{length}}$ is termed the *cephalic index* or *index of breadth*.

The *height* is usually measured from the basion to the bregma, and the proportion of height to length $\frac{(\text{height} \times 100)}{\text{length}}$ constitutes the *vertical* or *height index*.

In studying the face the principal points to be noticed are the proportion of its length and breadth, the shape of the orbits and of the anterior nasal aperture, and the degree of projection of the jaws.

The *length of the face* may be measured from the ophryon or nasion to the chin, or, if the mandible be wanting, to the alveolar point; while its *width* is represented by the distance between the zygomatic arches. By comparing the length with the width of the face, skulls may be divided into two groups; *dolichofacial* or *leptoprosop* (long faced) and *brachyfacial* or *chemoprosop* (short faced).

The *orbital index* signifies the proportion which the orbital height bears to the orbital width, thus:

$$\frac{\text{orbital height} \times 100}{\text{orbital width}}$$

The *nasal index* expresses the proportion which the width of the anterior nasal aperture bears to the height of the nose, the latter being measured from the nasion to the lower margin of the nasal aperture, thus:

$$\frac{\text{nasal width} \times 100}{\text{nasal height}}$$

The degree of projection of the jaws is determined by the *gnathic* or *alveolar index*, which represents the proportion between the basalveolar and basinasal lengths, thus:

$$\frac{\text{basalveolar length} \times 100}{\text{basinasal length}}$$

The following table, modified from that given by Duckworth,¹ illustrates how these different indices may be utilized in the classification of skulls:

Index.	Classification.	Nomenclature.	Examples.
1. Cephalic	Below 75 Between 75 and 80 Above 80	Dolichocephalic Mesaticephalic Brachycephalic	Kaffirs and Native Australians. Europeans and Chinese. Mongolians and Andamans.
2. Orbital	Below 84 Between 84 and 89 Above 89	Microseme Mesoseme Megaseme	Tasmanians and Native Australians. Europeans. Chinese and Polynesians.
3. Nasal	Below 48 Between 48 and 53 Above 53	Leptorhine Mesorhine Platyrrhine	Europeans. Japanese and Chinese. Negroes and Native Australians.
4. Gnathic	Below 98 Between 98 and 103 Above 103	Orthognathous Mesognathous Prognathous	Europeans. Chinese and Japanese. Native Australians.

Applied Anatomy.—Occasionally a protrusion of the brain or its membranes may take place through one of the sutures, owing to non-closure. When the protrusion consists of membranes only, and is filled with cerebrospinal fluid, it is called a *meningocele*; when it consists of brain as well as membranes, it is termed an *encephalocele*. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place between the centres of ossification of the occipital squama (see p. 231). They generally occur through the upper part of the vertical fissure, which is the last to close, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions are met with in other situations, as in the sagittal, lambdoidal, and other sutures, or through abnormal gaps at the sides or base of the skull.

The chief function of the skull is to protect the brain, and therefore those portions of the skull which are most exposed to external violence are thicker than those which are shielded from injury by overlying muscles. Thus, the skull-cap is thick and dense, whereas the temporal squamæ, being protected by the temporales muscles, and the inferior occipital fossæ, being shielded by the muscles at the back of the neck, are thin and fragile. Fracture of the skull is further prevented by its elasticity, its rounded shape, and its construction of a number of secondary elastic arches, each made up of a single bone. The manner in which vibrations are transmitted through the bones of the skull is also of importance as regards its protective mechanism, at all events as far as the base is concerned. In the vault, the bones being of a fairly equal thickness and density, vibrations are transmitted in a uniform manner in all directions, but in the base, owing to the varying thickness and density of the bones, this is not so; and therefore in this situation there are special buttresses which serve to carry the vibrations in certain definite directions. At the front of the skull, on either side, is the ridge which separates the anterior from the middle fossa of the base; and behind, the ridge or buttress which separates the middle from the posterior fossa; and if any violence is applied to the vault, the vibrations would be carried along these buttresses to the sella turcica, where they meet. This part has been termed the "centre of resistance," and here there is a special protective mechanism to guard the brain. The subarachnoid cavity at the base of the brain is dilated, and the cerebrospinal fluid which fills it acts as a water cushion to shield the brain from injury. In like manner, when violence is applied to the base of the skull, as in falls upon the feet, the vibrations are carried backward through the occipital crest, and forward through the basilar part of the occipital and body of the sphenoid to the vault of the skull.

Fractures of the skull are best considered as affecting either the vault or the base. Fractures of the vault generally involve the whole thickness of the bone; but sometimes the inner table alone is fractured, and portions of it driven inward. As a rule, in fractures of the skull, the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inward becomes broken up, and is more diffused by the time it reaches the inner table; the bone being in the form of an arch bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch, i. e., the outer table, and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be either simple, or starred and comminuted, and the fragments may be depressed or elevated. Cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture, a portion of the skull is

¹ *Morphology and Anthropology*, by W. L. H. Duckworth, M.A., Cambridge University Press.

broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if the fracture is also depressed, a fissure circumscribes the radiating lines, enclosing a portion of the skull. If this area is circular it is termed a "pond" fracture, and has probably been caused by a round instrument, as a life preserver or hammer; if elliptical in shape it is termed a "gutter" fracture, and owes its shape to the instrument which has produced it, as a poker. Fracture of the outer table alone only occurs in the region of the frontal sinuses where the two tables are completely separated.

Fractures of the base of the skull may be produced by *indirect* or *direct* violence. I. In cases of the former class the violence is applied to the vertex or some part of the cranial convexity, as when a person falls from a height on to his head and a fracture of the base results. The mechanism of this form of fracture was formerly explained by the doctrine of *contre-coup*, i. e., that the force was transmitted from one side of the skull to the other; but this view is no longer held, and there are at the present day two theories as to the mode of causation of these fractures. (a) According to Aran's theory of *irradiation* all fractures of the base are produced by a fissure, which starts from the point of injury and radiates to the base. There can be little doubt that many cases of fracture of the base, especially of the middle fossæ, are caused in this way, but it is insufficient to explain all, since instances have been met with of fracture of the base of the skull in which there has been no fracture of the vault. (b) To explain these cases, another theory, known as the *compression* or *bursting* theory, has been suggested. If a hollow, elastic sphere is compressed from above downward, it will bulge laterally, and, if the compression is sufficient, it will eventually burst in the situation where it bulges. Now, the skull is an elastic sphere, and when compression is applied to it, its diameter will be reduced along the line of greatest pressure and will therefore be increased in other directions, and may increase to such an extent that bursting occurs. In a hollow elastic sphere of uniform thickness, the bulging and subsequent bursting take place at the equatorial line midway between the two points of compression; but the skull is not of uniform thickness, and therefore the bulging and subsequent bursting take place at the weakest part.

II. Direct violence may be applied to the base of the skull in several different ways: by the impact of the vertebral column against the condyles of the occipital bone, in falls on the buttocks or feet; by the condyle of the mandible being driven against the mandibular fossa, in blows or falls on the chin; by the thrusting of a pointed instrument through the orbit or nose; by gunshot wounds through the mouth; and by a fall or a stab on the back of the head.

In the majority of cases the fracture is compound. The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighborhood of the parietal eminence, it runs downward through the parietal and the temporal squama and across the petrous portion, frequently traversing and implicating the internal acoustic meatus, to the foramen lacerum. From this it may pass across the body of the sphenoid, through the sella turcica, to the foramen lacerum of the other side, and may indeed travel around the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture explains the symptoms to which fracture in this region may give rise: thus, if the fissure pass across the internal acoustic meatus, injury to the facial and acoustic nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn and thus permit of the escape of the cerebrospinal fluid should there be a communication between the internal ear and the tympanic cavity together with rupture of the tympanic membrane, as is frequently the case: again, if the fissure pass across the sella turcica and the mucoperiosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal cavity, are generally the result of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forward, appears as a subconjunctival ecchymosis. If the roof of the nasal cavity be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebrospinal fluid from the nose, should the dura mater and arachnoid have been torn. In fractures of the posterior fossa, extravasation of blood may appear at the nape of the neck, beneath the muscles attached to the superior nuchal line of the occipital bone.

Diseases of the Skull.—An inflammatory condition affecting the bones and the pericranium together is generally caused by septic infection either of a scalp wound exposing and bruising the bone, or of a compound fracture, and is termed *septic osteomyelitis*. Occasionally it may occur independently of injury, and then follows the same course, and is due to the same causes as acute infective osteomyelitis in the long bones.

The most common chronic disease of the skull is due to syphilis. In *acquired syphilis* the disease usually occurs as *nodes*, which arise most commonly in the pericranium, but may also arise in the diploë, or more rarely on the inner surface of the skull. The formation of *gummata* under the periosteum generally leads to *caries*, which may be either limited, if the gumma is

localized, or widespread if the gumma is diffuse. The caries is often complicated by *necrosis*, for a condition of sclerosis is frequently set up in the surrounding bone, and the vessels in the Haversian canals become compressed and the vitality of the bone is interfered with; hence we often find a central necrosing area surrounded by a zone of caries. Large carious sequestra may be thrown off after prolonged suppuration, leaving considerable areas of the dura mater exposed. A common result of syphilitic disease of the skull is the production of large hard masses of bone on its surface, which give it a tuberculated appearance; in other cases, the skull presents a curious worm-eaten appearance; this is due to the fact that the osteogenetic powers of the pericranium are small and the formation of bone on the surface slight. In *hereditary syphilis*, in addition to the formation of gummata, which are usually of the subperiosteal variety, atrophic or hypertrophic changes may take place. In the atrophic cases the bone becomes abnormally thin, or even perforated. In the hypertrophic cases, a deposit of porous bone takes place around the anterior fontanelle; these deposits are separated by the coronal and sagittal sutures and are known as *Parrot's nodes*; such a skull has received the name of *natiform*, from its fancied resemblance to the buttocks.

Hypertrophic changes also occur in the skull in otitis deformans, acromegaly, leontiasis ossea, and in rickets. In rickets cases the skull becomes enlarged from the formation of periosteal outgrowths of soft tissue on the outer side of the skull. These deposits are very rich in blood-vessels, and occur between the ridges of the cranial bones and their centres of ossification, and are symmetrically arranged—often about the anterior fontanelle. The anterior fontanelle itself, instead of closing between the eighteenth and twenty-fourth months, as it normally does, remains patent in rickets until the third or even the sixth year. The general shape of the skull alters. The forehead is high and square, with prominent frontal eminences, and the head tends to be cubical or box-shaped; the enlargement of the head in rickets appears to be greater than it really is because the development of the facial bones is retarded. The base of the nose may appear sunken, from retarded development of the basis cranii. In marked cases of rickets these changes in the shape of the skull are permanent. In congenital hydrocephalus, or enlargement of the head due to the presence of excess of fluid in the ventricles of the brain, the cranium becomes globular, and its bones are thin and atrophic. They are often widely separated, the intervening fontanelles being much enlarged and partially filled in by numerous sutural bones; the atrophy of the cranium and brain may be so extreme that the light of a candle may be plainly visible through the whole thickness of the enlarged head.

The tympanic antrum, situated in the mastoid portion of the temporal bone, is often the seat of suppuration as a result of infection extending backward from the tympanic cavity. In such cases, the surgeon has to open the antrum in order to give exit to the pus; this he does by introducing his gouge in the suprameatal triangle (see p. 238). A line is drawn horizontally through the upper border of the bony external acoustic meatus, and a second vertically through the posterior wall of the meatus, and the gouge is applied in the angle where these two lines intersect; if the instrument be introduced at a higher level it will open the middle fossa of the skull. It is to be carried in the direction of the external acoustic meatus—inward, forward, and a little upward—for the distance of from 1 to 1.5 cm., when the antrum will be reached. In some cases of middle-ear trouble, septic thrombosis of the transverse sinus takes place, and it becomes necessary to work backward and explore the sinus.

In connection with the bones of the face a common malformation is *cleft palate*. The cleft usually starts posteriorly, and its most elementary form is a bifid uvula; or the cleft may extend through the soft palate; or the posterior part of the whole of the hard palate may be involved, the cleft extending as far forward as the incisive foramen. In the severest forms, the cleft extends through the alveolus and passes between the incisive or premaxillary bone and the rest of the maxilla; that is to say, between the lateral incisor and canine teeth. In some instances, the cleft runs between the central and lateral incisor teeth; and this has induced some anatomists to believe that the premaxillary bone is developed from two centres (Fig. 341) and not from one, as was stated on p. 262. The medial segment, bearing a central incisor, is called an *endognathion*; the lateral segment, bearing the lateral incisor, is called a *mesognathion*. The cleft may affect one or both sides; if the latter, the central part is frequently displaced forward and remains united to the septum of the nose, the deficiency in the alveolus being complicated with a cleft in the lip (hare-lip). On examining a cleft palate in which the alveolus is not implicated, the cleft will generally appear to be in the median line, but occasionally is unilateral and in some cases bilateral. To understand this it must be borne in mind that three processes are concerned in the formation of the palate—the palatine processes of the two maxillæ, which grow in horizontally and unite in the middle line, and the ethmovermerine process, which grows downward from the base of the skull and frontonasal process to unite with the palatine processes in the middle line. In

FIG. 341.—The premaxilla and its sutures. (After Albrecht.)

those cases where the palatine processes fail to unite with each other and with the medial process, the cleft of the palate is median; where one palatine process unites with the medial septum, the other failing to do so, the cleft in the palate is unilateral. In some cases where the palatine processes fail to meet in the middle, the ethmovomerine process grows downward between them and thus produces a bilateral cleft. Occasionally there may be a hole in the middle line of the hard palate, the anterior part of the hard and the soft palate being perfect; this is rare, because, as a rule, the union of the various processes progresses from before backward, and therefore the posterior part of the palate is more frequently defective than the anterior.

The bones of the face are sometimes fractured as the result of direct violence. Those most commonly broken are the nasal bones and the mandible; the latter is by far the most frequently fractured of all the facial bones. Fracture of the *nasal* bone is for the most part transverse, and takes place about 1.25 cm. from the free margin. The broken portion may be displaced backward or more generally to one side by the force which produced the lesion. The *zygomatic* bone is probably never broken alone—that is to say, without fracture of some of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs as a result of direct violence the fragments may be displaced inward. Fractures of the *maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the *mandible* is in the neighborhood of the canine tooth, as at this spot the bone is weakened by the deep socket for the root of this tooth; it is next most frequently fractured at the angle; then at the symphysis; and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. Displacement readily occurs and is difficult to rectify; it results in inequality in the line of the teeth and is commonly due to the muscles attached in the region of the symphysis dragging this portion downward.

The maxilla and the mandible are frequently the seat of necrosis; but the disease more often affects the lower than the upper jaw. It may be the result of periostitis from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it sometimes occurs in children after attacks of the exanthematous fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in the manufacture of matches. In the vast majority of cases, however, it is of dental origin.

Tumors originate in the jaw bones not infrequently, and may be either innocent or malignant. In the maxilla, cysts may occur in the antrum; or in either jaw in connection with the teeth; those connected with the roots of fully developed teeth are known as dental cysts; those connected with unerupted teeth, dentigerous cysts. Malignant tumors show a marked degree of malignancy when occurring in the maxilla. The results of distention of the walls of the maxillary antrum are given on page 260.

The maxilla sometimes requires removal for tumors or other conditions. In order to remove it, the patient should be placed in the recumbent position, in a good light, with the head and shoulders just raised. The central incisor tooth on the affected side is then extracted. One incision is begun just below the medial canthus of the eye and passes along the side of the nose, around the ala, and down the middle line of the upper lip into the mouth. A second incision is made from the commencement of the first, along the lower border of the orbit as far as the prominence of the zygomatic bone. The flap thus formed is reflected, so as to expose the bone. The periosteum attached along the lower margin of the orbit is now to be incised, and with the handle of the scalpel the periosteum covering the floor of the orbit is raised from the bone; for in all cases it is essential that this fibrous layer should not be removed. The mouth is now widely opened with a gag, and the mucous membrane covering the hard palate incised down to the bone in the middle line, and the soft palate separated from the hard. The surgeon having first separated the ala of the nose from its bony attachment, proceeds to divide the connections of the bone with the other bones of the face. They are (1) the junction with the zygomatic bone, the line of section being carried into the inferior orbital fissure; (2) the frontal process of the maxilla; a small portion of its upper extremity, connected with the nasal bone in front, the lacrimal bone behind, and the frontal bone above, being left; (3) the connection with the opposite maxilla and with the palatine bone in the roof of the mouth. The bone is now firmly grasped with lion-forceps; and by means of a rocking movement upward and downward, the remaining attachments of the orbital plate with the ethmoid, and of the back of the bone with the palatine, are broken through. Occasionally, in removing the maxilla, it will be found that the orbital plate can be saved, and this should always be done if possible. A horizontal saw-cut should then be made just below the infraorbital foramen.

THE EXTREMITIES.

The **extremities**, or limbs, are long, jointed appendages, each of which is connected to the trunk by one end, and is free in the rest of its extent. They are

four in number: an upper pair, connected with the thorax and subservient mainly to prehension; and a lower pair, connected with the vertebral column and intended for support and locomotion. Both pairs are constructed after one common type, but certain differences are observed between the upper and lower, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk constitute respectively the shoulder and pelvic girdles. The **shoulder girdle** or **girdle of the superior extremity** is formed by the scapulæ and clavicles, and is imperfect in front and behind. In front, however, it is completed by the upper end of the sternum, with which the medial ends of the clavicles articulate. Behind, it is widely imperfect, the scapulæ being connected to the trunk by muscles only. The **pelvic girdle** or **girdle of the inferior extremity** is formed by the hip bones, which articulate with each other in front, at the symphysis pubis. It is imperfect behind, but the gap is filled in by the upper part of the sacrum. The pelvic girdle, with the sacrum, is a complete ring, massive and comparatively rigid, in marked contrast to the lightness and mobility of the shoulder girdle.

THE BONES OF THE UPPER EXTREMITY (OSSA EXTREMITATIS SUPERIORIS).

The Clavicle (Clavicula; Collar Bone).

The **clavicle** (Figs. 342, 343) forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates medially with the manubrium sterni, and laterally with the acromion of the scapula.¹ It presents a double curvature, the convexity being directed forward at the sternal end, and the concavity at the scapular end. Its lateral third is flattened from above downward, while its medial two-thirds is of a rounded or prismatic form.

Sternal extremity

Acromial extremity

FIG. 342.—Left clavicle. Superior surface.

Lateral Third.—The lateral third has two surfaces, an upper and a lower; and two borders, an anterior and a posterior.

Surface.—The **upper surface** is flat, rough, and marked by impressions for the attachments of the Deltoides in front, and the Trapezius behind; between these impressions a small portion of the bone is subcutaneous. The **under surface** is flat. At its posterior border, near the point where the prismatic joins with the flattened portion, is a rough eminence, the **coracoid tuberosity** (*conoid tubercle*); this, in the natural position of the bone, surmounts the coracoid process of the

¹ The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore-limbs are used only for progression, but is present for the most part in animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating with either the scapula or sternum.

scapula, and gives attachment to the conoid ligament. From this tuberosity an oblique ridge, the **oblique or trapezoid ridge**, runs forward and lateralward, and afford attachment to the trapezoid ligament.

Borders.—The **anterior border** is concave, thin, and rough, and gives attachment to the Deltoides; at its medial part there is frequently a tubercle, the **deltoid tubercle**. The **posterior border** is convex, rough, thicker than the anterior, and gives attachment to the Trapezius.

Medial Two-thirds.—The medial two-thirds constitute the prismatic portion of the bone, which is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces.

Borders.—The **anterior border** is continuous with the anterior margin of the flat portion. Its lateral part is smooth, and corresponds to the interval between the attachments of the Pectoralis major and Deltoides; its medial part forms the lower boundary of an elliptical surface for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The **superior border** is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. Smooth and rounded laterally, it becomes rough toward the medial third for the attachment of the Sternocleidomastoideus, and ends at the upper angle of the sternal extremity. The **posterior or subclavian border** separates the posterior from the inferior surface, and extends from the coracoid tuberosity to the costal tuberosity; it forms the posterior boundary of the groove for the Subclavius, and gives attachment to a layer of cervical fascia which envelops the Omohyoideus.

Articular capsule

Articular capsule

FIG. 343.—Left clavicle. Inferior surface.

Surfaces.—The **anterior surface** is included between the superior and anterior borders. Its lateral part looks upward, and is continuous with the superior surface of the flattened portion; it is smooth, convex, and nearly subcutaneous, being covered only by the Platysma. Medially it is divided by a narrow subcutaneous area into two parts: a lower, elliptical in form, and directed forward, for the attachment of the Pectoralis major; and an upper for the attachment of the Sternocleidomastoideus. The **posterior or cervical surface** is smooth, and looks backward toward the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; medially, by the margin of the sternal extremity; and laterally, by the coracoid tuberosity. It is concave medio-laterally, and is in relation, by its lower part, with the transverse scapular vessels. This surface, at the junction of the curves of the bone, is also in relation with the brachial plexus of nerves and the subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sternohyoideus; and presents, near the middle, an oblique foramen directed lateralward, which transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior and another on the inferior surface. The **inferior or subclavian surface** is

bounded, in front, by the anterior border; behind, by the subclavian border. It is narrowed medially, but gradually increases in width laterally, and is continuous with the under surface of the flat portion. On its medial part is a broad rough surface, the **costal tuberosity** (*rhomboid impression*), rather more than 2 cm. in length, for the attachment of the costoclavicular ligament. The rest of this surface is occupied by a groove, which gives attachment to the Subclavius; the coracoclavicular fascia, which splits to enclose the muscle, is attached to the margins of the groove. Not infrequently this groove is subdivided longitudinally by a line which gives attachment to the intermuscular septum of the Subclavius.

The Sternal Extremity (*extremitas sternalis; internal extremity*).—The sternal extremity of the clavicle is triangular in form, directed medialward, and a little downward and forward; it presents an articular facet, concave from before backward, convex from above downward, which articulates with the manubrium sterni through the intervention of an articular disk. The lower part of the facet is continued on to the inferior surface of the bone as a small semi-oval area for articulation with the cartilage of the first rib. The circumference of the articular surface is rough, for the attachment of numerous ligaments; the upper angle gives attachment to the articular disk.

The Acromial Extremity (*extremitas acromialis; outer extremity*).—The acromial extremity presents a small, flattened, oval surface directed obliquely downward, for articulation with the acromion of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromioclavicular ligaments.

In the female, the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In those persons who perform considerable manual labor it becomes thicker and more curved, and its ridges for muscular attachment are prominently marked.

Structure.—The clavicle consists of cancellous tissue, enveloped by a compact layer, which is much thicker in the intermediate part than at the extremities of the bone.

Ossification.—The clavicle begins to ossify before any other bone in the body; it is ossified from three centres—viz., two primary centres, a medial and a lateral, for the body,¹ which appear during the fifth or sixth week of fetal life; and a secondary centre for the sternal end, which appears about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Applied Anatomy.—The clavicle is very frequently fractured, since it is much exposed to violence, and is the only bony connection between the upper limb and the trunk, acting as a buttress to keep the point of the shoulder away from the thorax. It is, moreover, slender, and is very superficial. It may be broken by direct or indirect violence. The most common cause is, however, indirect violence, as the result of force applied to the hand or shoulder, and the bone then gives way at the junction of its lateral with its intermediate third, that is to say, at the junction of the two curves, for this is its weakest part. The fracture is generally oblique, and the displacement of the lateral fragment is downward, forward, and medialward. The deformity is mainly due to the weight of the arm acting upon the fragment when the buttress-like action of the bone is gone, assisted by the muscles which pass from the thorax to the upper extremity. The medial fragment, as a rule, is little displaced. Beneath the bone the main vessels of the upper limb and the great nerve cords of the brachial plexus lie on the first rib and are liable to be wounded, especially in fracture from direct violence, when the force of the blow drives the broken ends inward. Fortunately the subclavius intervenes between these structures and the clavicle, and often protects them from injury.

The clavicle is occasionally the seat of sarcomatous tumors, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it forward. The removal of the lateral part is comparatively easy, but resection of the medial part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its deep surface.

Great deformity of the clavicle may be met with in rickets, the natural curvatures of the bone being exaggerated until it takes on an S-shape, and "green-stick" fracture is not uncommonly seen associated therewith.

¹ Mall, *American Journal of Anatomy*, vol. v; Fawcett, *Journal of Anatomy and Physiology*, vol. xlvii.

The Scapula (Shoulder Blade).

The **scapula** forms the posterior part of the shoulder girdle. It is a flat, triangular bone, with two surfaces, three borders, and three angles.

Surfaces.—The **costal** or **ventral surface** (Fig. 344) presents a broad concavity, the **subscapular fossa**. The medial two-thirds of the fossa are marked by several oblique ridges, which run lateralward and upward. The ridges give attachment

*Coracoacromial
ligament*

FIG. 344.—Left scapula. Costal surface.

to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis. The lateral third of the fossa is smooth and covered by the fibres of this muscle. The fossa is separated from the vertebral border by smooth triangular areas at the medial and inferior angles, and in the interval between these by a narrow ridge which is often deficient. These triangular areas and the

intervening ridge afford attachment to the Serratus anterior. At the upper part of the fossa is a transverse depression, where the bone appears to be bent on itself along a line at right angles to and passing through the centre of the glenoid cavity, forming a considerable angle, called the **subscapular angle**; this gives greater strength to the body of the bone by its arched form, while the summit of the arch serves to support the spine and acromion.

FIG. 345.—Left scapula. Dorsal surface.

The **dorsal surface** (Fig. 345) is arched from above downward, and is subdivided into two unequal parts by the spine; the portion above the spine is called the **supraspinatous fossa**, and that below it the **infraspinatous fossa**.

The **supraspinatous fossa**, the smaller of the two, is concave, smooth, and broader at its vertebral than at its humeral end; its medial two-thirds give origin to the Supraspinatus.

The **infraspinatous fossa** is much larger than the preceding; toward its vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, while near the axillary border is a deep groove which runs from the upper toward the lower part. The medial two-thirds of the fossa give origin to the Infraspinatus; the lateral third is covered by this muscle.

The dorsal surface is marked near the axillary border by an elevated ridge, which runs from the lower part of the glenoid cavity, downward and backward to the vertebral border, about 2.5 cm. above the inferior angle. The ridge serves for the attachment of a fibrous septum, which separates the Infraspinatus from the Teres major and Teres minor. The surface between the ridge and the axillary border is narrow in the upper two-thirds of its extent, and is crossed near its centre by a groove for the passage of the scapular circumflex vessels; it affords attachment to the Teres minor. Its lower third presents a broader, somewhat triangular surface, which gives origin to the Teres major, and over which the Latissimus dorsi glides; frequently the latter muscle takes origin by a few fibres from this part. The broad and narrow portions above alluded to are separated by an oblique line, which runs from the axillary border, downward and backward, to meet the elevated ridge: to it is attached a fibrous septum which separates the Teres muscles from each other.

The Spine (*spina scapulae*).—The spine is a prominent plate of bone, which crosses obliquely the medial four-fifths of the dorsal surface of the scapula at its upper part, and separates the supra- from the infraspinatous fossa. It begins at the vertical border by a smooth, triangular area over which the tendon of insertion of the lower part of the Trapezius glides, and, gradually becoming more elevated, ends in the acromion, which overhangs the shoulder-joint. The spine is triangular, and flattened from above downward, its apex being directed toward the vertebral border. It presents two surfaces and three borders. Its **superior surface** is concave; it assists in forming the supraspinatous fossa, and gives origin to part of the Supraspinatus. Its **inferior surface** forms part of the infraspinatous fossa, gives origin to a portion of the Infraspinatus, and presents near its centre the orifice of a nutrient canal. Of the three borders, the **anterior** is attached to the dorsal surface of the bone; the **posterior**, or **crest of the spine**, is broad, and presents two lips and an intervening rough interval. The Trapezius is attached to the superior lip, and a rough tubercle is generally seen on that portion of the spine which receives the tendon of insertion of the lower part of this muscle. The Deltoideus is attached to the whole length of the inferior lip. The interval between the lips is subcutaneous and partly covered by the tendinous fibres of these muscles. The **lateral border**, or **base**, the shortest of the three, is slightly concave; its edge, thick and round, is continuous above with the under surface of the acromion, below with the neck of the scapula. It forms the medial boundary of the **great scapular notch**, which serves to connect the supra- and infraspinatous fossæ.

The Acromion.—The acromion forms the summit of the shoulder, and is a large, somewhat triangular or oblong process, flattened from behind forward, projecting at first lateralward, and then curving forward and upward, so as to overhang the glenoid cavity. Its **superior surface**, directed upward, backward, and lateralward, is convex, rough, and gives attachment to some fibres of the Deltoideus, and in the rest of its extent is subcutaneous. Its **inferior surface** is smooth and concave. Its **lateral border** is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoideus. Its **medial border**, shorter than the lateral, is concave, gives attachment to a portion of the Trapezius, and presents about its centre a small, oval surface for articulation with the acromial end of the clavicle.

Its **apex**, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coracoacromial ligament.

Borders.—Of the *three* borders of the scapula, the **superior** is the shortest and thinnest; it is concave, and extends from the medial angle to the base of the coracoid process. At its lateral part is a deep, semicircular notch, the **scapular notch**, formed partly by the base of the coracoid process. This notch is converted into a foramen by the superior transverse ligament, and serves for the passage of the suprascapular nerve; sometimes the ligament is ossified. The adjacent part of the superior border affords attachment to the Omohyoideus. The **axillary border** is the thickest of the three. It begins above at the lower margin of the glenoid cavity, and inclines obliquely downward and backward to the inferior angle. Immediately below the glenoid cavity is a rough impression, the **infraglenoid tuberosity**, about 2.5 cm. in length, which gives origin to the long head of the *Triceps brachii*; in front of this is a longitudinal groove, which extends as far as the lower third of this border, and affords origin to part of the *Subscapularis*. The inferior third is thin and sharp, and serves for the attachment of a few fibres of the *Teres major* behind, and of the *Subscapularis* in front. The **vertebral border** is the longest of the three, and extends from the medial to the inferior angle. It is arched, intermediate in thickness between the superior and the axillary borders, and the portion of it above the spine forms an obtuse angle with the part below. This border presents an anterior and a posterior lip, and an intermediate narrow area. The anterior lip affords attachment to the *Serratus anterior*; the posterior lip, to the *Supraspinatus* above the spine, the *Infraspinatus* below; the area between the two lips, to the *Levator scapulae* above the triangular surface at the commencement of the spine, to the *Rhomboideus minor* on the edge of that surface, and to the *Rhomboideus major* below it; this last is attached by means of a fibrous arch, connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the border.

Angles.—Of the *three* angles, the **medial**, formed by the junction of the superior and vertebral borders, is thin, smooth, rounded, inclined somewhat lateralward, and gives attachment to a few fibres of the *Levator scapulae*. The **inferior angle**, thick and rough, is formed by the union of the vertebral and axillary borders; its dorsal surface affords attachment to the *Teres major* and frequently to a few fibres of the *Latissimus dorsi*. The **lateral angle** is the thickest part of the bone, and is sometimes called the head of the scapula. On it is a shallow pyriform, articular surface, the **glenoid cavity**, which is directed lateralward and forward and articulates with the head of the humerus; it is broader below than above and its vertical diameter is the longest. The surface is covered with cartilage in the recent state; and its margins, slightly raised, give attachment to a fibro-cartilaginous structure, the **glenoidal labrum**, which deepens the cavity. At its apex is a slight elevation, the **supraglenoid tuberosity**, to which the long head of the *Biceps brachii* is attached. The **neck** of the scapula is the slightly constricted portion which surrounds the head; it is more distinct below and behind than above and in front.

The Coracoid Process (*processus coracoideus*).—The coracoid process is a thick curved process attached by a broad base to the upper part of the neck of the scapula; it runs at first upward and medialward; then, becoming smaller, it changes its direction, and projects forward and lateralward. The ascending portion, flattened from before backward, presents in front a smooth concave surface, across which the *Subscapularis* passes. The horizontal portion is flattened from above downward; its upper surface is convex and irregular, and gives attachment to the *Pectoralis minor*; its under surface is smooth; its medial and lateral borders are rough; the former gives attachment to the *Pectoralis minor* and the latter to the coracoacromial ligament; the apex is embraced by the conjoined tendon of origin of the

Coracobrachialis and short head of the Biceps brachii and gives attachment to the coracoclavicular fascia. On the medial part of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forward and lateralward, on to the upper surface of the horizontal portion, is an elevated ridge for the attachment of the trapezoid ligament.

Structure.—The head, processes, and the thickened parts of the bone, contain cancellous tissue; the rest consists of a thin layer of compact tissue. The central part of the supraspinatous fossa and the upper part of the infraspinatous fossa, but especially the former, are usually so thin as to be semitransparent; occasionally the bone is found wanting in this situation, and the adjacent muscles are separated only by fibrous tissue.

Ossification (Fig. 346).—The scapula is ossified from *seven* or more centres: one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle.

3
1

FIG. 346.—Plan of ossification of the scapula. From seven centres.

Ossification of the body begins about the second month of fetal life, by the formation of an irregular quadrilateral plate of bone, immediately behind the glenoid cavity. This plate extends so as to form the chief part of the bone, the spine growing up from its dorsal surface about the third month. At birth, a large part of the scapula is osseous, but the glenoid cavity, the coracoid process, the acromion, the vertebral border, and the inferior angle are cartilaginous. From the fifteenth to the eighteenth month after birth, ossification takes place in the middle of the coracoid process, which as a rule becomes joined with the rest of the bone about the fifteenth year. Between the fourteenth and twentieth years, ossification of the remaining parts takes place in quick succession, and usually in the following order; first, in the root of the coracoid process, in the form of a broad scale; secondly, near the base of the acromion; thirdly, in the inferior angle and contiguous part of the vertebral border; fourthly, near the extremity of the acromion; fifthly, in the vertebral border. The base of the acromion is formed by an extension from the spine; the two separate nuclei of the acromion unite, and then join with the extension from the spine. The upper third of the glenoid cavity is ossified from a separate centre (subcoracoid), which makes its appearance between the tenth and eleventh years and joins between the sixteenth and the eighteenth. Further, an epiphysial plate appears for the lower part of the glenoid cavity, while the tip of the

coracoid process frequently presents a separate nucleus. These various epiphyses are joined to the bone by the twenty-fifth year. Failure of bony union between the acromion and spine sometimes occurs, the junction being effected by fibrous tissue, or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union, it is probable that the detached segment was never united to the rest of the bone.

Articulations.—The scapula articulates with the humerus and clavicle.

Applied Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layers of muscles by which it is encased, and the elasticity of the ribs on which it rests. Fracture of the neck is also uncommon. The most frequent course of a fracture is from the scapular notch to the infraglenoid tuberosity, and it derives its principal interest from its simulation of a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. The acromion is more frequently broken than any other part of the bone, and fibrous union is very liable to follow.

The presence of "winged scapulae" (*scapulae alatae*) described in thin persons of feeble muscular development in whom the lower angles of the blade bones project unduly, is due partly to abnormal roundness of the thoracic wall ("barrel-shaped chest," p. 226), and partly to weakness and flaccidity of the *Latissimus dorsi* and *Serratus anterior*. The shoulders are held low in these subjects, and the clavicles slope downward and forward, carrying with them the scapulae, which fit ill to the posterior wall of the chest and so tend to project from it.

Tumors of various kinds grow from the scapula. Of the innocent form probably the osteomata are the most common. When an osteoma grows from the venter of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. Sarcomatous tumors sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T-shaped incision, and the flaps being reflected, the removal is commenced from the vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be readily secured.

The Humerus (Arm Bone).

The humerus (Figs. 347, 348) is the longest and largest bone of the upper extremity; it is divisible into a **body** and **two extremities**.

Upper Extremity.—The upper extremity consists of a large rounded *head* joined to the body by a constricted portion called the **neck**, and two eminences, the **greater** and **lesser tubercles**.

The Head (*caput humeri*).—The head, nearly hemispherical in form,¹ is directed upward, medialward, and a little backward, and articulates with the glenoid cavity of the scapula. The circumference of its articular surface is slightly constricted, and is termed the **anatomical neck**, in contradistinction to a constriction below the tubercles called the **surgical neck** which is frequently the seat of fracture. Fracture of the anatomical neck rarely occurs.

The **Anatomical Neck** (*collum anatomicum*) is obliquely directed, forming an obtuse angle with the body. It is best marked in the lower half of its circumference; in the upper half it is represented by a narrow groove separating the head from the tubercles. It affords attachment to the articular capsule of the shoulder-joint, and is perforated by numerous vascular foramina.

The Greater Tubercle (*tuberculum majus; greater tuberosity*).—The greater tubercle is situated lateral to the head and lesser tubercle. Its upper surface is rounded and marked by three flat impressions: the highest of these gives insertion to the *Supraspinatus*; the middle to the *Infraspinatus*; the lowest one, and the body of the bone for about 2.5 cm. below it, to the *Teres minor*. The lateral surface of the greater tubercle is convex, rough, and continuous with the lateral surface of the body.

The Lesser Tubercle (*tuberculum minus; lesser tuberosity*).—The lesser tubercle, although smaller, is more prominent than the greater: it is situated in front, and

¹ Though the head is nearly hemispherical in form, its margin, as Humphry has shown, is by no means a true circle. Its greatest diameter is, from the top of the intertubercular groove in a direction downward, medialward, and backward. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upward, lateralward, and forward.

is directed medialward and forward. Above and in front it presents an impression for the insertion of the tendon of the Subscapularis.

The tubercles are separated from each other by a deep groove, the **intertubercular groove** (*bicipital groove*), which lodges the long tendon of the Biceps brachii and transmits a branch of the anterior humeral circumflex artery to the shoulder-joint. It runs obliquely downward, and ends near the junction of the upper with the middle third of the bone. In the recent state its upper part is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder-joint; its lower portion gives insertion to the tendon of the Latissimus dorsi. It is deep and narrow above, and becomes shallow and a little broader as it descends. Its lips are called, respectively, the **crests of the greater and lesser tubercles** (*bicipital ridges*), and form the upper parts of the anterior and medial borders of the body of the bone.

The Body or Shaft (*corpus humeri*).—The body is almost cylindrical in the upper half of its extent, prismatic and flattened below, and has three borders and three surfaces.

Borders.—The **anterior border** runs from the front of the greater tubercle above to the coronoïd fossa below, separating the antero-medial from the antero-lateral surface. Its upper part is a prominent ridge, the crest of the greater tubercle; it serves for the insertion of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the deltoid tuberosity; below, it is smooth and rounded, affording attachment to the Brachialis.

The **lateral border** runs from the back part of the greater tubercle to the lateral epicondyle, and separates the antero-lateral from the posterior surface. Its upper half is rounded and indistinctly marked, serving for the attachment of the lower part of the insertion of the Teres minor, and below this giving origin to the lateral head of the Triceps brachii; its centre is traversed by a broad but shallow oblique depression, the **radial sulcus** (*musculospiral groove*). Its lower part forms a prominent, rough margin, a little curved from behind forward, the **lateral supracondylar ridge**, which presents an anterior lip for the origin of the Brachioradialis above, and Extensor carpi radialis longus below, a posterior lip for the Triceps brachii, and an intermediate ridge for the attachment of the lateral intermuscular septum.

FIG. 348.—Left humerus. Posterior view.

The **medial border** extends from the lesser tubercle to the medial epicondyle. Its upper third consists of a prominent ridge, the **crest of the lesser tubercle**, which gives insertion to the tendon of the *Teres major*. About its centre is a slight impression for the insertion of the *Coracobrachialis*, and just below this is the entrance of the nutrient canal, directed downward; sometimes there is a second nutrient canal at the commencement of the radial sulcus. The inferior third of this border is raised into a slight ridge, the **medial supracondylar ridge**, which becomes very prominent below; it presents an anterior lip for the origins of the *Brachialis* and *Pronator teres*, a posterior lip for the medial head of the *Triceps brachii*, and an intermediate ridge for the attachment of the medial intermuscular septum.

Surfaces.—The **antero-lateral surface** is directed lateralward above, where it is smooth, rounded, and covered by the *Deltoides*; forward and lateralward below, where it is slightly concave from above downward, and gives origin to part of the *Brachialis*. About the middle of this surface is a rough, triangular elevation, the **deltoid tuberosity** for the insertion of the *Deltoides*; below this is the **radial sulcus**, directed obliquely from behind, forward, and downward, and transmitting the radial nerve and profunda artery.

The **antero-medial surface**, less extensive than the antero-lateral, is directed medialward above, forward and medialward below; its upper part is narrow, and forms the floor of the intertubercular groove which gives insertion to the tendon of the *Latissimus dorsi*; its middle part is slightly rough for the attachment of some of the fibres of the tendon of insertion of the *Coracobrachialis*; its lower part is smooth, concave from above downward, and gives origin to the *Brachialis*.¹

The **posterior surface** appears somewhat twisted, so that its upper part is directed a little medialward, its lower part backward and a little lateralward. Nearly the whole of this surface is covered by the lateral and medial heads of the *Triceps brachii*, the former arising above, the latter below the radial sulcus.

The Lower Extremity.—The lower extremity is flattened from before backward, and curved slightly forward; it ends below in a broad, articular surface, which is divided into two parts by a slight ridge. Projecting on either side are the lateral and medial epicondyles. The **articular surface** extends a little lower than the epicondyles, and is curved slightly forward; its medial extremity occupies a lower level than the lateral. The lateral portion of this surface consists of a smooth, rounded eminence, named the **capitulum of the humerus**; it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone. On the medial side of this eminence is a shallow groove, in which is received the medial margin of the head of the radius. Above the front part of the capitulum is a slight depression, the **radial fossa**, which receives the anterior border of the head of the radius, when the forearm is flexed. The medial portion of the articular surface is named the **trochlea**, and presents a deep depression between two well-marked borders; it is convex from before backward, concave from side to side, and occupies the anterior, lower, and posterior parts of the extremity. The lateral border separates it from the groove which articulates with the margin of the head of the radius. The medial border is thicker, of greater length, and consequently more prominent, than the lateral. The grooved portion of the articular surface fits accurately within the semilunar notch of the ulna; it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined

¹ A small, hook-shaped process of bone, the *supracondylar process*, varying from 2 to 20 mm. in length, is not infrequently found projecting from the antero-medial surface of the body of the humerus 5 cm. above the medial epicondyle. It is curved downward and forward, and its pointed end is connected to the medial border, just above the medial epicondyle, by a fibrous band, which gives origin to a portion of the *Pronator teres*; through the arch completed by this fibrous band the median nerve and brachial artery pass, when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial. A well-marked groove is usually found behind the process, in which the nerve and artery are lodged. This arch is the homologue of the supracondylar foramen found in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region.

obliquely downward and forward toward the medial side. Above the front part of the trochlea is a small depression, the **coronoid fossa**, which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlea is a deep triangular depression, the **olecranon fossa**, in which the summit of the olecranon is received in extension of the forearm. These fossæ are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated by a **supratrochlear foramen**; they are lined in the recent state by the synovial membrane of the elbow-joint, and their margins afford attachment to the anterior and posterior ligaments of this articulation. The **lateral epicondyle** is a small, tuberculated eminence, curved a little forward, and giving attachment to the radial collateral ligament of the elbow-joint, and to a tendon common to the origin of the Supinator and some of the Extensor muscles. The **medial epicondyle**, larger and more prominent than the lateral, is directed a little backward; it gives attachment to the ulnar collateral ligament of the elbow-joint, to the Pronator teres, and to a common tendon of origin of some of the Flexor muscles of the forearm; the ulnar nerve runs in a groove on the back of this epicondyle. The epicondyles are continuous above with the supracondylar ridges.

Structure.—The extremities consist of cancellous tissue, covered with a thin, compact layer (Fig. 349); the body is composed of a cylinder of compact tissue, thicker at the centre than toward the extremities, and contains a large medullary canal which extends along its whole length.

Ossification (Figs. 350, 351).—The humerus is ossified from *eight* centres, one for each of the following parts: the body, the head, the greater tubercle, the lesser tubercle, the capitulum, the trochlea, and one for each epicondyle. The centre for the body appears near the middle of the bone in the eighth week of fetal life, and soon extends toward the extremities. At birth the humerus is ossified in nearly its whole length, only the extremities remaining cartilaginous. During the first year, sometimes before birth, ossification commences in the head of the bone, and during the third year the centre for the greater tubercle, and during the fifth that for the lesser tubercle, make their appearance. By the sixth year the centres for the head and tubercles have joined, so as to form a single large epiphysis, which fuses with the body about the twentieth year. The lower end of the humerus is ossified as follows. At the end of the second year ossification begins in the capitulum, and extends medialward, to form the chief part of the articular end of the bone; the centre for the medial part of the trochlea appears about the age of twelve. Ossification begins in the medial epicondyle about the fifth year, and in the lateral about the thirteenth or fourteenth year. About the sixteenth or seventeenth year, the lateral epicondyle and both portions of the articulating surface, having already joined, unite with the body, and at the eighteenth year the medial epicondyle becomes joined to it.

Epiphyseal line

FIG. 349.—Longitudinal section of head of left humerus.

Articulations.—The humerus articulates with the scapula, ulna, and radius.

Applied Anatomy.—There are several points of surgical interest connected with the ossification of the humerus. The upper end, though the first to ossify, is the last to join the body, and the length of the bone is mainly due to growth from the upper epiphyseal plate. Hence, in cases of amputation of the arm in young subjects, the humerus continues to grow considerably, and the end of the bone which immediately after the operation was covered with a thick cushion of soft tissue begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of about 5 cm. of the bone, and even after this operation a recurrence of the conical stump may take place. The region of the upper epiphysis, moreover, is the common site for the growth of tumors, both innocent and malignant.

Fractures of the humerus present several points of surgical interest. The bone may be broken by direct or indirect violence, like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other bone of this class. It is usually

the body, just below the insertion of the Deltoides, which is thus broken, and the accident has been known to happen from throwing a stone. Fractures of the upper end may take place either through the anatomical or surgical neck, or a separation of the greater tubercle may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. Fracture of the surgical neck of the bone is not uncommon, and impaction may occur; on the other hand, the upper end of the lower fragment may be displaced into the axilla and may damage the vessels or nerves. The fracture somewhat closely simulates dislocation of the shoulder-joint, but can be distinguished by the fact that the head of the bone remains in its normal position and the great tubercle still forms the most prominent point of the shoulder. Separation of the upper epiphysis sometimes occurs in the young subject, and is marked by a characteristic deformity, consisting in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the diaphysis. In fractures of

the body of the humerus the lesion may take place at any point, but appears to be more common in the lower than the upper part of the bone. The points of interest in connection with these fractures are: (1) that the radial nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union, which is believed to be more common in the humerus than in any other bone. An important distinction to make in fractures of the lower end is between those that involve the elbow-joint and those which do not; the former are always serious, as they may lead to impairment of the utility of the limb; they include the T-shaped fracture and oblique fractures which involve the articular surface. Those which do not involve the joint are the transverse fracture above the epicondyles, and the so-called epitrochlear fracture, where the tip of the medial epicondyle is broken off, generally from direct violence.

The Ulna (Elbow Bone).

The **ulna** (Figs. 353, 354) is a long bone, prismatic in form, placed at the medial side of the forearm, parallel with the radius. It is divisible into a **body** and **two extremities**. Its upper extremity, of great thickness and strength, forms

a large part of the elbow-joint; the bone diminishes in size from above downward, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an articular disk.

The Upper Extremity (*proximal extremity*) (Fig. 352).—The upper extremity presents two curved processes, the **olecranon** and the **coronoid process**; and two concave, articular cavities, the **semilunar** and **radial notches**.

The Olecranon (*olecranon process*).—The olecranon is a large, thick, curved eminence, situated at the upper and back part of the ulna. It is bent forward at the summit so as to present a prominent lip which is received into the olecranon fossa of the humerus in extension of the forearm. Its **base** is contracted where it joins the body and the narrowest part of the upper end of the ulna. Its **posterior surface**, directed backward, is triangular, smooth, subcutaneous, and covered by a bursa. Its **superior surface** is of quadrilateral form, marked behind by a rough impression for the insertion of the Triceps brachii; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its **anterior surface** is smooth, concave, and forms the upper part of the semilunar notch. Its **borders** present continuations of the groove on the margin of the superior surface; they serve for the attachment of ligaments, viz., the back part of the ulnar collateral ligament medially, and the posterior ligament laterally. From the medial border a part of the Flexor carpi ulnaris arises; while to the lateral border the Anconæus is attached.

Olecranon

The Coronoid Process (*processus coronoideus*).

—The coronoid process is a triangular eminence projecting forward from the upper and front part of the ulna. Its **base** is continuous with the body of the bone, and of considerable strength. Its **apex** is pointed, slightly curved upward, and in flexion of the forearm is received into the coronoid fossa of the humerus. Its **upper surface** is smooth, concave, and forms the lower part of the semilunar notch. Its **antero-inferior surface** is concave, and marked by a rough impression for the insertion of the Brachialis. At the junction of this surface with the front of the body is a rough eminence, the **tuberosity of the ulna**, which gives insertion to a part of the Brachialis; to the lateral border of this tuberosity the oblique cord is attached. Its **lateral surface** presents a narrow, oblong, articular depression, the **radial notch**. Its **medial surface**, by its prominent, free margin, serves for the attachment of part of the ulnar collateral ligament. At the front part of this surface is a small rounded eminence for the origin of one head of the Flexor digitorum sublimis; behind the eminence is a depression for part of the origin of the Flexor digitorum profundus; descending from the eminence is a ridge which gives origin to one head of the Pronator teres. Frequently, the Flexor pollicis longus arises from the lower part of the coronoid process by a rounded bundle of muscular fibres.

*Coronoid
process*

FIG. 352.—Upper extremity of left ulna

The Semilunar Notch (*incisura semilunaris; greater sigmoid cavity*).—The semilunar notch is a large depression, formed by the olecranon and the coronoid process, and serving for articulation with the trochlea of the humerus. About the middle of either side of this notch is an indentation, which contracts it somewhat, and

indicates the junction of the olecranon and the coronoid process. The notch is concave from above downward, and divided into a medial and a lateral portion by a smooth ridge running from the summit of the olecranon to the tip of the coronoid process. The medial portion is the larger, and is slightly concave transversely; the lateral is convex above, slightly concave below.

The Radial Notch (*incisura radialis; lesser sigmoid cavity*).—The radial notch is a narrow, oblong, articular depression on the lateral side of the coronoid process; it receives the circumferential articular surface of the head of the radius. It is concave from before backward, and its prominent extremities serve for the attachment of the annular ligament.

The Body or Shaft (*corpus ulnae*).—The body at its upper part is prismatic in form, and curved so as to be convex behind and lateralward; its central part is straight; its lower part is rounded, smooth, and bent a little lateralward. It tapers gradually from above downward, and has three borders and three surfaces.

Borders.—The **volar border** (*margo volaris; anterior border*) begins above at the prominent medial angle of the coronoid process, and ends below in front of the styloid process. Its upper part, well-defined, and its middle portion, smooth and rounded, give origin to the Flexor digitorum profundus; its lower fourth serves for the origin of the Pronator quadratus. This border separates the volar from the medial surface.

The **dorsal border** (*margo dorsalis; posterior border*) begins above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and ends below at the back of the styloid process; it is well-marked in the upper three-fourths, and gives attachment to an aponeurosis which affords a common origin to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor digitorum profundus; its lower fourth is smooth and rounded. This border separates the medial from the dorsal surface.

The **interosseous crest** (*crista interossea; external or interosseous border*) begins above by the union of two lines, which converge from the extremities of the radial notch and enclose between them a triangular space for the origin of part of the Supinator; it ends below at the head of the ulna. Its upper part is sharp, its lower fourth smooth and rounded. This crest gives attachment to the interosseous membrane, and separates the volar from the dorsal surface.

Surfaces.—The **volar surface** (*facies volaris; anterior surface*), much broader above than below, is concave in its upper three-fourths, and gives origin to the Flexor digitorum profundus; its lower fourth, also concave, is covered by the Pronator quadratus. The lower fourth is separated from the remaining portion by a ridge, directed obliquely downward and medialward, which marks the extent of origin of the Pronator quadratus. At the junction of the upper with the middle third of the bone is the nutrient canal, directed obliquely upward.

The **dorsal surface** (*facies dorsalis; posterior surface*) directed backward and lateralward, is broad and concave above; convex and somewhat narrower in the middle; narrow, smooth, and rounded below. On its upper part is an oblique ridge, which runs from the dorsal end of the radial notch, downward to the dorsal border; the triangular surface above this ridge receives the insertion of the Anconaeus, while the upper part of the ridge affords attachment to the Supinator. Below this the surface is subdivided by a longitudinal ridge, sometimes called the **perpendicular line**, into two parts: the medial part is smooth, and covered by the Extensor carpi ulnaris; the lateral portion, wider and rougher, gives origin from above downward to the Supinator, the Abductor pollicis longus, the Extensor pollicis longus, and the Extensor indicis proprius.

The **medial surface** (*facies medialis; internal surface*) is broad and concave above, narrow and convex below. Its upper three-fourths give origin to the Flexor digitorum profundus; its lower fourth is subcutaneous.

The Lower Extremity (*distal extremity*).—The lower extremity of the ulna is small, and presents two eminences; the lateral and larger is a rounded, articular eminence, termed the head of the ulna; the medial, narrower and more projecting, is a non-articular eminence, the styloid process. The **head** presents an articular surface, part of which, of an oval or semilunar form, is directed downward, and articulates with the upper surface of the triangular articular disk which separates it from the wrist-joint; the remaining portion, directed lateralward, is narrow, convex, and received into the ulnar notch of the radius. The **styloid process** projects from the medial and back part of the bone; it descends a little lower than the head, and its rounded end affords attachment to the ulnar collateral ligament of the wrist-joint. The head is separated from the styloid process by a depression for the attachment of the apex of the triangular articular disk, and behind, by a shallow groove for the tendon of the Extensor carpi ulnaris.

FIG. 355.—Plan of ossification of the ulna.
From three centres.

FIG. 356.—Epiphysial lines of ulna in a young adult.
Lateral aspect. The lines of attachment of the articular capsules are in blue.

Structure.—The structure of the ulna is similar to that of the other long bones.

Ossification (Figs. 355, 356).—The ulna is ossified from *three* centres: one each for the body, the inferior extremity, and the top of the olecranon. Ossification begins near the middle of the body, about the eighth week of fetal life, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year, a centre appears in the middle of the head, and soon extends into the styloid process. About the tenth year, a centre appears in the olecranon near its extremity, the chief part of this process being formed by an upward extension of the body. The upper epiphysis joins the body about the sixteenth, the lower about the twentieth year.

Articulations.—The ulna articulates with the humerus and radius.

The Radius.

The **radius** (Figs. 353, 354) is situated on the lateral side of the ulna, which exceeds it in length and size. Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist-

joint. It is a long bone, prismatic in form and slightly curved longitudinally. It has a body and two extremities.

The Upper Extremity (*proximal extremity*).—The upper extremity presents a head, neck, and tuberosity. The **head** is of a cylindrical form, and on its upper surface is a shallow cup or fovea for articulation with the capitulum of the humerus. The circumference of the head is smooth; it is broad medially where it articulates with the radial notch of the ulna, narrow in the rest of its extent, which is embraced by the annular ligament. The head is supported on a round, smooth, and constricted portion called the **neck**, on the back of which is a slight ridge for the insertion of part of the Supinator. Beneath the neck, on the medial side, is an eminence, the **radial tuberosity**; its surface is divided into a posterior, rough portion, for the insertion of the tendon of the Biceps brachii, and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The Body or Shaft (*corpus radii*).—The body is prismoid in form, narrower above than below, and slightly curved, so as to be convex lateralward. It presents three borders and three surfaces.

Borders.—The **volar border** (*margo volaris; anterior border*) extends from the lower part of the tuberosity above to the anterior part of the base of the styloid process below, and separates the volar from the lateral surface. Its upper third is prominent, and from its oblique direction has received the name of the **oblique line of the radius**; it gives origin to the Flexor digitorum sublimis and Flexor pollicis longus; the surface above the line gives insertion to part of the Supinator. The middle third of the volar border is indistinct and rounded. The lower fourth is prominent, and gives insertion to the Pronator quadratus, and attachment to the dorsal carpal ligament; it ends in a small tubercle, into which the tendon of the Brachioradialis is inserted.

The **dorsal border** (*margo dorsalis; posterior border*) begins above at the back of the neck, and ends below at the posterior part of the base of the styloid process; it separates the posterior from the lateral surface. It is indistinct above and below, but well-marked in the middle third of the bone.

The **interosseous crest** (*crista interossea; internal or interosseous border*) begins above, at the back part of the tuberosity, and its upper part is rounded and indistinct; it becomes sharp and prominent as it descends, and at its lower part divides into two ridges which are continued to the anterior and posterior margins of the ulnar notch. To the posterior of the two ridges the lower part of the interosseous membrane is attached, while the triangular surface between the ridges gives insertion to part of the Pronator quadratus. This crest separates the volar from the dorsal surface, and gives attachment to the interosseous membrane.

Surface.—The **volar surface** (*facies volaris; anterior surface*) is concave in its upper three-fourths, and gives origin to the Flexor pollicis longus; it is broad and flat in its lower fourth, and affords insertion to the Pronator quadratus. A prominent ridge limits the insertion of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the volar radiocarpal ligament. At the junction of the upper and middle thirds of the volar surface is the nutrient foramen, which is directed obliquely upward.

The **dorsal surface** (*facies dorsalis; posterior surface*) is convex, and smooth in the upper third of its extent, and covered by the Supinator. Its middle third is broad, slightly concave, and gives origin to the Abductor pollicis longus above, and the Extensor pollicis brevis below. Its lower third is broad, convex, and covered by the tendons of the muscles which subsequently run in the grooves on the lower end of the bone.

The **lateral surface** (*facies lateralis; external surface*) is convex throughout its entire extent. Its upper third gives insertion to the Supinator. About its centre is a rough ridge, for the insertion of the Pronator teres. Its lower part is narrow, and covered by the tendons of the Abductor pollicis longus and Extensor pollicis brevis.

The Lower Extremity.—The lower extremity is large, of quadrilateral form, and provided with two articular surfaces—one below, for the carpus, and another at the medial side, for the ulna. The carpal articular surface is triangular, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the lateral, triangular, articulates with the navicular bone; the medial, quadrilateral, with the lunate bone. The articular surface for the ulna is called the **ulnar notch (sigmoid cavity) of the radius**; it is narrow, concave, smooth, and articulates with the head of the ulna. These two articular surfaces are separated by a prominent ridge, to which the base of the triangular articular disk is attached; this disk separates the wrist-joint from the distal radioulnar articulation. This end of the bone has three non-articular surfaces—volar, dorsal, and lateral. The **volar surface**, rough and irregular, affords attachment to the volar radiocarpal ligament. The **dorsal surface** is convex, affords attachment to the dorsal radiocarpal ligament, and is marked by three grooves. Enumerated from the lateral side, the first groove is broad, but shallow, and subdivided into two by a slight ridge; the lateral of these two transmits the tendon of the Extensor carpi radialis longus, the medial the tendon of the Extensor carpi radialis brevis. The second is deep but narrow, and bounded laterally by a sharply defined ridge; it is directed obliquely from above downward and lateralward, and transmits the tendon of the Extensor pollicis longus. The third is broad, for the passage of the tendons of the Extensor indicis proprius and Extensor digitorum communis. The **lateral surface** is prolonged obliquely downward into a strong, conical projection, the **styloid process**, which gives attachment by its base to the tendon of the Brachioradialis, and by its apex to the radial collateral ligament of the wrist-joint. The lateral surface of this process is marked by a flat groove, for the tendons of the Abductor pollicis longus and Extensor pollicis brevis.

Structure.—The structure of the radius is like that of the other long bones.

Ossification (Figs. 357, 358).—The radius is ossified from *three* centres: one for the body, and one for either extremity. That for the body makes its appearance near the centre of the bone, during the eighth week of fetal life. About the end of the second year, ossification commences in the lower end; and at the fifth year, in the upper end. The upper epiphysis fuses with the body at the age of seventeen or eighteen years, the lower about the age of twenty. An additional centre sometimes found in the radial tuberosity, appears about the fourteenth or fifteenth year.

Articulations.—The radius articulates with *four* bones: the humerus, ulna, navicular, and lunate.

Applied Anatomy of the Ulna and Radius.—The two bones of the forearm are more often broken together, than is either the radius or ulna separately. It is therefore convenient to consider in the first instance the fractures of both bones and subsequently the principal fractures which take place in either bone. Fractures of both bones may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius as a rule gives way, though both bones may suffer. Fracture from indirect force generally takes place somewhere about the middle of the bones, while that from direct violence may occur at any part, but is most frequent in the lower half of the bones. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other. Anterior and posterior splints are applied in these cases, and should be rather wider than the limb, so as to prevent any side pressure on the bones.

The special fractures of the ulna are: (1) Fracture of the olecranon, which is usually caused by direct violence, by falls on the elbow with the forearm flexed, but occasionally by muscular action in sudden contraction of the Triceps brachii; the most common site of this fracture is at the constricted portion where the olecranon joins the body of the bone, and the fracture is usually transverse; but any part may be broken, and even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. If the fibrous structures around the process are not torn the displacement is slight, otherwise the olecranon may be drawn up for a very considerable distance. (2) Fracture of the coronoid process may occur as a complication of dislocation backward of the bones of the forearm, but it is doubtful if it ever takes place as an uncomplicated injury. (3) Fractures of the body of the ulna may occur at any part, but usually take place at

or a little below the middle of the bone. They are generally the result of direct violence, but may occur as a complication of dislocation of the radius. (4) The styloid process may be knocked off by direct violence.

Fractures of the radius may consist of: (1) Fracture of the head of the bone; this for the most part takes place in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck also may occur, but is usually complicated with other injury. (3) Fractures of the body of the radius are very common, and may take place at any part of the bone. They may be caused by direct or indirect violence. In fracture of the upper third of the body—that is to say, above the insertion of the Pronator teres—the displacement is very great. The upper fragment is strongly supinated by the biceps and supinator and flexed by the biceps; while the lower fragment is pronated and drawn toward the ulna by the two pronators. If such a fracture be put up in the ordinary position, midway between supination and pronation, the bone will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movement of supination will result; the limb should therefore be put up with the forearm supinated. (4) The most important fracture of the

FIG. 357.—Plan of ossification of the radius.
From three centres.

FIG. 358.—Epiphysal lines of radius in a young adult. Anterior aspect. The line of attachment of the articular capsule of the wrist-joint is in blue.

radius is that of the lower end (*Colles' fracture*). The fracture is transverse, and generally takes place about 2.5 cm. from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than in the male. In consequence of the manner in which the fracture is caused, the upper fragment is driven into the lower, and impaction commonly is the result; excess of violence may, however, disimpact, the lower fragment being split into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and *Colles' fracture* may be distinguished from other injuries in this neighborhood—especially dislocation of the wrist, with which they are liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural conditions of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna. After fracture or separation of the epiphysis the styloid process of the radius is on the same level as, or on a higher level than, that of the ulna, whereas it would be unaltered in position in dislocation. Reduction in the case of *Colles' fracture* is usually easily effected by traction on the hand, the limb being subsequently splinted with the hand deflected toward the ulnar side.

THE HAND.

The skeleton of the hand (Figs. 359, 360) is subdivided into three segments: the **carpus** or wrist bones; the **metacarpus** or bones of the palm; and the **phalanges** or bones of the digits.

The Carpus (Ossa Carpi).

The **carpal bones**, eight in number, are arranged in two rows. Those of the proximal row, from the radial to the ulnar side, are named the **navicular**, **lunate**, **triangular**, and **pisiform**; those of the distal row, in the same order, are named the **greater multangular**, **lesser multangular**, **capitate**, and **hamate**.

Common Characteristics of the Carpal Bones.—Each bone (excepting the pisiform) presents six surfaces. Of these the *volar* or *anterior* and the *dorsal* or *posterior surfaces* are rough, for ligamentous attachment; the dorsal surfaces being the broader, except in the navicular and lunate. The *superior* or *proximal*, and *inferior* or *distal surfaces* are articular, the superior generally convex, the inferior concave; the *medial* and *lateral surfaces* are also articular where they are in contact with contiguous bones, otherwise they are rough and tuberculated. The structure in all is similar, viz., cancellous tissue enclosed in a layer of compact bone.

Bones of the Proximal Row (upper row).—**The Navicular Bone** (*os naviculare manus; scaphoid bone*) (Fig. 361).—The navicular bone is the largest bone of the proximal row, and has received its name from its fancied resemblance to a boat. It is situated at the radial side of the carpus, its long axis being from above downward, lateralward, and forward. The **superior surface** is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The **inferior surface**, directed downward, lateralward, and backward, is also smooth, convex, and triangular, and is divided by a slight ridge into two parts, the lateral articulating with the greater multangular, the medial with the lesser multangular. On the **dorsal surface** is a narrow, rough groove, which runs the entire length of the bone, and serves for the attachment of ligaments. The **volar surface** is concave above, and elevated at its lower and lateral part into a rounded projection, the **tubercle**, which is directed forward and gives attachment to the transverse carpal ligament and sometimes origin to a few fibres of the Abductor pollicis brevis. The **lateral surface** is rough and narrow, and gives attachment to the radial collateral ligament of the wrist. The **medial surface** presents two articular facets; of these, the superior or smaller is flattened of semilunar form, and articulates with the lunate bone; the inferior or larger is concave, forming with the lunate a concavity for the head of the capitate bone.

Articulations.—The navicular articulates with *five* bones: the radius proximally, greater and lesser multangulans distally, and capitate and lunate medially.

The Lunate Bone (*os lunatum; semilunar bone*) (Fig. 362).—The lunate bone may be distinguished by its deep concavity and crescentic outline. It is situated in the centre of the proximal row of the carpus, between the navicular and triangular. The **superior surface**, convex and smooth, articulates with the radius. The **inferior surface** is deeply concave, and of greater extent from before backward than transversely: it articulates with the head of the capitate, and, by a long, narrow facet (separated by a ridge from the general surface), with the hamate. The **dorsal** and **volar surfaces** are rough, for the attachment of ligaments, the former being the broader, and of a somewhat rounded form. The **lateral surface** presents a narrow, flattened, semilunar facet for articulation with the navicular. The **medial surface** is marked by a smooth, quadrilateral facet, for articulation with the triangular.

Articulations.—The lunate articulates with *five* bones: the radius proximally, capitate and hamate distally, navicular laterally, and triangular medially.

The Triangular Bone (*os triquetrum; cuneiform bone*) (Fig. 363).—The triangular bone may be distinguished by its pyramidal shape, and by an oval isolated facet for articulation with the pisiform bone. It is situated at the upper and ulnar side of the carpus. The **superior surface** presents a medial, rough, non-articular portion, and a lateral convex articular portion which articulates with the triangular articular disk of the wrist. The **inferior surface**, directed lateralward, is concave, sinuously curved, and smooth for articulation with the hamate. The **dorsal surface** is rough

FIG. 359.—Bones of the left hand. Volar surface.

for the attachment of ligaments. The **volar surface** presents, on its medial part, an oval facet, for articulation with the pisiform; its lateral part is rough for ligamentous attachment. The **lateral surface**, the base of the pyramid, is marked by a flat, quadrilateral facet, for articulation with the lunate. The **medial surface**, the summit of the pyramid, is pointed and roughened, for the attachment of the ulnar collateral ligament of the wrist.

Articulations.—The triangular articulates with *three* bones: the lunate laterally, the pisiform in front, the hamate distally; and with the triangular articular disk which separates it from the lower end of the ulna.

FIG. 361.—The left navicular bone.

The Pisiform Bone (*os pisiforme*) (Fig. 364).—The pisiform bone may be known by its small size, and by its presenting a single articular facet. It is situated on a plane anterior to the other carpal bones and is spheroidal in form. Its dorsal

FIG. 362.—The left lunate bone.

surface presents a smooth, oval facet, for articulation with the triangular: this facet approaches the superior, but not the inferior border of the bone. The volar surface is rounded and rough, and gives attachment to the transverse carpal ligament,

FIG. 363.—The left triangular bone.

FIG. 364.—The left pisiform bone.

and to the Flexor carpi ulnaris and Abductor digiti quinti. The lateral and medial surfaces are also rough, the former being concave, the latter usually convex.

Articulation.—The pisiform articulates with *one* bone, the triangular.

FIG. 365.—The left greater multangular bone.

Bones of the Distal Row (*lower row*).—The Greater Multangular Bone (*os multangulum majus; trapezium*) (Fig. 365).—The greater multangular bone may be distinguished by a deep groove on its volar surface. It is situated at the radial

side of the carpus, between the navicular and the first metacarpal bone. The **superior surface** is directed upward and medialward; medially it is smooth, and articulates with the navicular; laterally it is rough and continuous with the lateral surface. The **inferior surface** is oval, concave from side to side, convex from before backward, so as to form a saddle-shaped surface for articulation with the base of the first metacarpal bone. The **dorsal surface** is rough. The **volar surface** is narrow and rough. At its upper part is a deep groove, running from above obliquely downward and medialward; it transmits the tendon of the Flexor carpi radialis, and is bounded laterally by an oblique ridge. This surface gives origin to the Opponens pollicis and to the Abductor and Flexor pollicis brevis; it also affords attachment to the transverse carpal ligament. The **lateral surface** is broad and rough, for the attachment of ligaments. The **medial surface** presents two facets; the upper, large and concave, articulates with the lesser multangular; the lower, small and oval, with the base of the second metacarpal.

Articulations.—The greater multangular articulates with *four* bones: the navicular proximally, the first metacarpal distally, and the lesser multangular and second metacarpal medially.

The Lesser Multangular Bone (*os multangulum minus; trapezoid bone*) (Fig. 366).—The lesser multangular is the smallest bone in the distal row. It may be known by its wedge-shaped form, the broad end of the wedge constituting the dorsal, the narrow end the volar surface; and by its having four articular facets touching each other, and separated by sharp edges. The **superior surface**, quadrilateral, smooth, and slightly concave, articulates with the navicular. The **inferior surface** articulates with the proximal end of the second metacarpal bone; it is convex from side to side, concave from before backward and subdivided by an elevated ridge into two unequal facets. The **dorsal and volar surfaces** are rough for the attachment of ligaments, the former being the larger of the two. The **lateral surface**, convex and smooth, articulates with the greater multangular. The **medial surface** is concave and smooth in front, for articulation with the capitate; rough behind, for the attachment of an interosseous ligament.

FIG. 366.—The left lesser multangular bone.

Articulations.—The lesser multangular articulates with *four* bones: the navicular proximally, second metacarpal distally, greater multangular laterally, and capitate medially.

FIG. 367.—The left capitate bone.

The Capitate Bone (*os capitatum; os magnum*) (Fig. 367).—The capitate bone is the largest of the carpal bones, and occupies the centre of the wrist. It presents, above, a rounded portion or head, which is received into the concavity formed by

the navicular and lunate; a constricted portion or neck; and below this, the body. The **superior surface** is round, smooth, and articulates with the lunate. The **inferior surface** is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third being the largest. The **dorsal surface** is broad and rough. The **volar surface** is narrow, rounded, and rough, for the attachment of ligaments and a part of the Adductor pollicis obliquus. The **lateral surface** articulates with the lesser multangular by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Above this is a deep, rough groove, forming part of the neck, and serving for the attachment of ligaments; it is bounded superiorly by a smooth, convex surface, for articulation with the navicular. The **medial surface** articulates with the hamate by a smooth, concave, oblong facet, which occupies its posterior and superior parts; it is rough in front, for the attachment of an interosseous ligament.

Articulations.—The capitate articulates with *seven* bones: the navicular and lunate proximally, the second, third, and fourth metacarpals distally, the lesser multangular on the radial side, and the hamate on the ulnar side.

FIG. 368.—The left hamate bone.

The Hamate Bone (*os hamatum*; *unciform bone*) (Fig. 368).—The hamate bone may be readily distinguished by its wedge-shaped form, and the hook-like process which projects from its volar surface. It is situated at the medial and lower angle of the carpus, with its base downward, resting on the fourth and fifth metacarpal bones, and its apex directed upward and lateralward. The **superior surface**, the apex of the wedge, is narrow, convex, smooth, and articulates with the lunate. The **inferior surface** articulates with the fourth and fifth metacarpal bones, by concave facets which are separated by a ridge. The **dorsal surface** is triangular and rough for ligamentous attachment. The **volar surface** presents, at its lower and ulnar side, a curved, hook-like process, the **hamulus**, directed forward and lateralward. This process gives attachment, by its apex, to the transverse carpal ligament and the Flexor carpi ulnaris; by its medial surface to the Flexor brevis and Opponens digiti quinti; its lateral side is grooved for the passage of the Flexor tendons into the palm of the hand. It is one of the four eminences on the front of the carpus to which the transverse carpal ligament of the wrist is attached; the others being the pisiform medially, the oblique ridge of the greater multangular, and the tubercle of the navicular laterally. The **medial surface** articulates with the triangular bone by an oblong facet, cut obliquely from above, downward and medialward. The **lateral surface** articulates with the capitate by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

Articulations.—The hamate articulates with *five* bones: the lunate proximally, the fourth and fifth metacarpals distally, the triangular medially, the capitate laterally.

The Metacarpus.

The **metacarpus** consists of five cylindrical bones which are numbered from the lateral side (*ossa metacarpalia I-V*); each consists of a body and two extremities.

Common Characteristics of the Metacarpal Bones. **The Body** (*corpus; shaft*).—The body is prismoid in form, and curved, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces: medial, lateral, and dorsal. The **medial** and **lateral surfaces** are concave, for the attachment of the Interossei, and separated from one another by a prominent anterior ridge. The **dorsal surface** presents in its distal two-thirds a smooth, triangular, flattened area which is covered in the recent state, by the tendons of the Extensor muscles. This surface is bounded by two lines, which commence in small tubercles situated on either side of the digital extremity, and, passing upward, converge and meet some distance above the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two sloping surfaces for the attachment of the Interossei dorsales. To the tubercles on the digital extremities are attached the collateral ligaments of the metacarpophalangeal joints.

The **Base** or **Carpal Extremity** (*basis*) is of a cuboidal form, and broader behind than in front: it articulates with the carpus, and with the adjoining metacarpal bones; its **dorsal** and **volar surfaces** are rough, for the attachment of ligaments.

The **Head** or **Digital Extremity** (*capitulum*) presents an oblong surface markedly convex from before backward, less so transversely, and flattened from side to side; it articulates with the proximal phalanx. It is broader, and extends farther upward, on the volar than on the dorsal aspect, and is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the collateral ligament of the metacarpophalangeal joint. The **dorsal surface**, broad and flat, supports the Extensor tendons; the **volar surface** is grooved in the middle line for the passage of the Flexor tendons, and marked on either side by an articular eminence continuous with the terminal articular surface.

Characteristics of the Individual Metacarpal Bones.—**The First Metacarpal Bone** (*os metacarpale I; metacarpal bone of the thumb*) (Fig. 369) is shorter and stouter than the others, diverges to a greater degree from the carpus, and its volar surface is directed toward the palm. The body is flattened and broad on its dorsal surface, and does not present the ridge which is found on the other metacarpal bones; its volar surface is concave from above downward. On its radial border is inserted the Opponens pollicis; its ulnar border gives origin to the lateral head of the first Interosseus dorsalis. The **base** presents a concavo-convex surface, for articulation with the greater multangular; it has no facets on its sides, but on its radial side is a tubercle for the insertion of the Abductor pollicis longus. The **head** is less convex than those of the other metacarpal bones, and is broader from side to side than from before backward. On its volar surface are two articular eminences, of which the lateral is the larger, for the two sesamoid bones in the tendons of the Flexor pollicis brevis.

The Second Metacarpal Bone (*os metacarpale II; metacarpal bone of the index finger*) (Fig. 370) is the longest, and its base the largest, of the four remaining bones. Its **base** is prolonged upward and medialward, forming a prominent ridge.

For greater multangular For greater multangular
FIG. 369.—The first metacarpal.
(Left.)

It presents four articular facets: three on the upper surface and one on the ulnar side. Of the facets on the upper surface the intermediate is the largest and is concave from side to side, convex from before backward for articulation with the lesser multangular; the lateral is small, flat and oval for articulation with the greater multangular; the medial, on the summit of the ridge, is long and narrow for articulation with the capitate. The facet on the ulnar side articulates with the third metacarpal. The Extensor carpi radialis longus is inserted on the dorsal surface and the Flexor carpi radialis on the volar surface of the base.

For 4th metacarpal

FIG. 371.—The third metacarpal. (Left.)

The Third Metacarpal Bone (*os metacarpale III*; *metacarpal bone of the middle finger*) (Fig. 371) is a little smaller than the second. The dorsal aspect of its base presents on its radial side a pyramidal eminence, the **styloid process**, which extends upward behind the capitate; immediately distal to this is a rough surface for the attachment of the Extensor carpi radialis brevis. The carpal articular facet is concave behind, flat in front, and articulates with the capitate. On the radial side is a smooth, concave facet for articulation with the second metacarpal, and on the ulnar side two small oval facets for the fourth metacarpal.

The Fourth Metacarpal Bone (*os metacarpale IV*; *metacarpal bone of the ring finger*) (Fig. 372) is shorter and smaller than the third. The base is small and quadrilateral; its superior surface presents two facets, a large one medially for articulation with the hamate, and a small one laterally for the capitate. On the radial side are two oval facets, for articulation with the third metacarpal; and on the ulnar side a single concave facet, for the fifth metacarpal.

The Fifth Metacarpal Bone (*os metacarpale V*; *metacarpal bone of the little finger*) (Fig. 373) presents on its base one facet on its superior surface, which is concavo-convex and articulates with the hamate, and one on its radial side, which articulates with the fourth metacarpal. On its ulnar side is a prominent tubercle for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the body is divided by an oblique ridge, which extends from near the ulnar side of the base to the radial side of the head. The lateral part of this surface serves for the attach-

ment of the fourth *Interosseus dorsalis*; the medial part is smooth, triangular, and covered by the *Extensor tendons* of the little finger.

FIG. 373.—The fifth metacarpal. (Left.)

Articulations.—Besides their phalangeal articulations, the metacarpal bones articulate as follows: the first with the greater multangular; the second with the greater multangular, lesser multangular, capitate and third metacarpal; the third with the capitate and second and fourth metacarpals; the fourth with the capitate, hamate, and third and fifth metacarpals; and the fifth with the hamate and fourth metacarpal.

The Phalanges of the Hand (*Phalanges Digitorum Manus*).

The **phalanges** are fourteen in number, three for each finger, and two for the thumb. Each consists of a body and two extremities. The **body** tapers from above downward, is convex posteriorly, concave in front from above downward, flat from side to side; its sides are marked by rough ridges which give attachment to the fibrous sheaths of the *Flexor tendons*. The **proximal extremities** of the bones of the first row present oval, concave articular surfaces, broader from side to side than from before backward. The **proximal extremity** of each of the bones of the second and third rows presents a double concavity separated by a median ridge. The **distal extremities** are smaller than the proximal, and each ends in two condyles separated by a shallow groove; the articular surface extends farther on the volar than on the dorsal surface, a condition best marked in the bones of the first row.

The **ungual phalanges** are convex on their dorsal and flat on their volar surfaces; they are recognized by their small size, and by a roughened, elevated surface of a horseshoe form on the volar surface of the distal extremity of each which serves to support the sensitive pulp of the finger.

Articulations.—In the four fingers the phalanges of the first row articulate with those of the second row and with the metacarpals; the phalanges of the second row with those of the first and third rows, and the unguinal phalanges with those of the second row. In the thumb, which has only two phalanges, the first phalanx articulates by its proximal extremity with the metacarpal bone and by its distal with the unguinal phalanx.

Ossification of the Bones of the Hand.—The **carpal bones** are each ossified from a single centre, and ossification proceeds in the following order (Fig. 374): in the capitate and hamate, during the first year, the former preceding the latter; in the triangular, during the third year; in the lunate and greater multangular, during the fifth year, the former preceding the latter; in the navicular, during the sixth year; in the lesser multangular, during the eighth year; and in the pisiform, about the twelfth year.

Occasionally an additional bone, the *os centrale*, is found on the back of the carpus, lying between the navicular, lesser multangular, and capitate. During the second month of fetal life it is represented by a small cartilaginous nodule, which usually fuses with the cartilaginous navicular. Sometimes the styloid process of the third metacarpal is detached and forms an additional ossicle.

The **metacarpal bones** are each ossified from *two* centres: one for the body and one for the distal extremity of each of the second, third, fourth, and fifth bones; one for the body and one for the base of the first metacarpal bone.¹ The first metacarpal bone is therefore ossified in the same manner as the phalanges, and this has led some anatomists to regard the thumb as being made up of three phalanges, and not of a metacarpal bone and two phalanges. Ossification commences in the middle of the body about the eighth or ninth week of fetal life, the centres for the second and third metacarpals being the first, and that for the first metacarpal, the last, to appear; about the third year the distal extremities of the metacarpals of the fingers, and the base of the metacarpal of the thumb, begin to ossify; they unite with the bodies about the twentieth year.

FIG. 374.—Plan of ossification of the hand.

The **phalanges** are each ossified from *two* centres: one for the body, and one for the proximal extremity. Ossification begins in the body, about the eighth week of fetal life. Ossification of the proximal extremity commences in the bones of the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united in each row between the eighteenth and twentieth years.

In the ungual phalanges the centres for the bodies appear at the distal extremities of the phalanges, instead of at the middle of the bodies, as in the other phalanges. Moreover, of all the bones of the hand, the ungual phalanges are the first to ossify.

Applied Anatomy.—The carpal bones are little liable to fracture, except from extreme violence, when the parts are so comminuted as to necessitate amputation. Occasionally they are the

¹ Allen Thomson demonstrated the fact that the first metacarpal bone is often developed from three centres. that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis visible at the age of seven or eight years. He also stated that there are traces of a proximal epiphysis in the second metacarpal bone, *Journal of Anatomy and Physiology*, 1869.

seat of tuberculous disease. The metacarpal bones and the phalanges are sometimes broken from direct violence. There are two diseases of the metacarpal bones and phalanges which require special mention on account of their frequent occurrence. One is tuberculous dactylitis, consisting in a deposit of tuberculous material in the medullary canal, expansion of the bone, with subsequent caseation and necrosis. The other is chondroma, which is perhaps more commonly found in connection with the metacarpal bones and phalanges than with any other bones. The tumors are usually multiple, and spring from beneath the periosteum about the epiphysal plate.

THE BONES OF THE LOWER EXTREMITY (OSSA EXTREMITATIS INFERIORIS).

The Hip Bone (Os Coxæ; Innominate Bone).

The **hip bone** is a large, flattened, irregularly shaped bone, constricted in the centre and expanded above and below. It meets its fellow on the opposite side in the middle line in front, and together they form the sides and anterior wall of the pelvic cavity. It consists of three parts, the **ilium**, **ischium**, and **pubis**, which are distinct from each other in the young subject, but are fused in the adult; the union of the three parts takes place in and around a large cup-shaped articular cavity, the **acetabulum**, which is situated near the middle of the outer surface of the bone. The **ilium**, so-called because it supports the flank, is the superior broad and expanded portion which extends upward from the acetabulum. The **ischium** is the lowest and strongest portion of the bone; it proceeds downward from the acetabulum, expands into a large tuberosity, and then, curving forward, forms, with the pubis, a large aperture, the **obturator foramen**. The **pubis** extends medialward and downward from the acetabulum and articulates in the middle line with the bone of the opposite side: it forms the front of the pelvis and supports the external organs of generation.

The Ilium (*os ilii*).—The ilium is divisible into two parts, the **body** and the **ala**; the separation is indicated on the internal surface by a curved line, the **arcuate line**, and on the external surface by the margin of the acetabulum.

The Body (*corpus oss. ilii*).—The body enters into the formation of the acetabulum, of which it forms rather less than two-fifths. Its **external surface** is partly articular, partly non-articular; the articular segment forms part of the lunate surface of the acetabulum, the non-articular portion contributes to the acetabular fossa. The **internal surface** of the body is part of the wall of the lesser pelvis and gives origin to some fibres of the Obturator internus. Below, it is continuous with the pelvic surfaces of the ischium and pubis, only a faint line indicating the place of union.

The Ala (*ala oss. ilii*).—The ala is the large expanded portion which bounds the greater pelvis laterally. It presents for examination two surfaces—an external and an internal—a crest, and two borders—an anterior and a posterior. The **external surface** (Fig. 375), known as the **dorsum ilii**, is directed backward and lateralward behind, and downward and lateralward in front. It is smooth, convex in front, deeply concave behind; bounded above by the crest, below by the upper border of the acetabulum, in front and behind by the anterior and posterior borders. This surface is crossed in an arched direction by three lines—the posterior, anterior, and inferior gluteal lines. The **posterior gluteal line** (*superior curved line*), the shortest of the three, begins at the crest, about 5 cm. in front of its posterior extremity; it is at first distinctly marked, but as it passes downward to the upper part of the greater sciatic notch, where it ends, it becomes less distinct, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and gives origin to a portion of the Glutæus maximus; the lower part is smooth and has no muscular fibres attached to it. The **anterior gluteal line** (*middle curved line*), the longest of the three, begins at the crest, about 4 cm. behind its

The **internal surface** (Fig. 376) of the ala is bounded above by the crest, below, by the arcuate line; in front and behind, by the anterior and posterior borders. It presents a large, smooth, concave surface, called the **iliac fossa**, which gives origin to the Iliacus and is perforated at its inner part by a nutrient canal; and below this a smooth, rounded border, the **arcuate line**, which runs downward, forward, and medialward. Behind the iliac fossa is a rough surface, divided into two

FIG. 376.—Right hip bone. Internal surface.

portions, an anterior and a posterior. The **anterior surface** (*auricular surface*), so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a similar surface on the side of the sacrum. The posterior portion, known as the **iliac tuberosity**, is elevated and rough, for the attachment of the posterior sacroiliac ligaments and for the origins of the Sacrospinalis and Multifidus. Below and in front of the auricular surface is the

preauricular sulcus, more commonly present and better marked in the female than in the male; to it is attached the pelvic portion of the anterior sacroiliac ligament.

The **crest** of the ilium is convex in its general outline but is sinuously curved, being concave inward in front, concave outward behind. It is thinner at the centre than at the extremities, and ends in the **anterior** and **posterior superior iliac spines**. The surface of the crest is broad, and divided into external and internal lips, and an intermediate line. About 5 cm. behind the anterior superior iliac spine there is a prominent tubercle on the outer lip. To the external lip are attached the Tensor fasciae latae, Obliquus externus abdominis, and Latissimus dorsi, and along its whole length the fascia lata; to the intermediate line the Obliquus internus abdominis; to the internal lip, the fascia iliaca, the Transversus abdominis, Quadratus lumborum, Sacrospinalis, and Iliacus.

The **anterior border** of the ala is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the **anterior superior iliac spine**; its outer border gives attachment to the fascia lata, and the Tensor fasciae latae, its inner border, to the Iliacus; while its extremity affords attachment to the inguinal ligament and gives origin to the Sartorius. Beneath this eminence is a notch from which the Sartorius takes origin and across which the lateral femoral cutaneous nerve passes. Below the notch is the **anterior inferior iliac spine**, which ends in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris and to the iliofemoral ligament of the hip-joint. Medial to the anterior inferior spine is a broad, shallow groove, over which the Iliacus and Psoas major pass. This groove is bounded medially by an eminence, the **iliopectineal eminence**, which marks the point of union of the ilium and pubis.

The **posterior border** of the ala, shorter than the anterior, also presents two projections separated by a notch, the **posterior superior iliac spine** and the **posterior inferior iliac spine**. The former serves for the attachment of the oblique portion of the posterior sacroiliac ligaments and the Multifidus; the latter corresponds with the posterior extremity of the auricular surface. Below the posterior inferior spine is a deep notch, the **greater sciatic notch**.

The Ischium (*os ischii*).—The ischium forms the lower and back part of the hip bone. It is divisible into three portions—a **body** and **two rami**.

The Body (*corpus oss. ischii*).—The body enters into and constitutes a little more than two-fifths of the acetabulum. Its **external surface** forms part of the lunate surface of the acetabulum and a portion of the acetabular fossa. Its **internal surface** is part of the wall of the lesser pelvis; it gives origin to some fibres of the Obturator internus. Its anterior border projects as the **posterior obturator tubercle**; from its posterior border there extends backward a thin and pointed triangular eminence, the **ischial spine**, more or less elongated in different subjects. The external surface of the spine gives attachment to the Gemellus superior, its internal surface to the Coccygeus, Levator ani, and the pelvic fascia; while to the pointed extremity the sacrospinous ligament is attached. Above the spine is a large notch, the **greater sciatic notch**, converted into a foramen by the sacrospinous ligament; it transmits the Piriformis, the superior and inferior gluteal vessels and nerves, the sciatic and posterior femoral cutaneous nerves, the internal pudendal vessels, and nerve, and the nerves to the Obturator internus and Quadratus femoris. Of these, the superior gluteal vessels and nerve pass out above the Piriformis, the other structures below it. Below the spine is a smaller notch, the **lesser sciatic notch**; it is smooth, coated in the recent state with cartilage, the surface of which presents two or three ridges corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen by the sacrotuberous and sacrospinous ligaments, and transmits the tendon of the

Obturator internus, the nerve which supplies that muscle, and the internal pudendal vessels and nerve.

The Superior Ramus (*ramus superior oss. ischii; descending ramus*).—The superior ramus projects downward and backward from the body and presents for examination three surfaces: external, internal, and posterior. The **external surface** is quadrilateral in shape. It is bounded *above* by a groove which lodges the tendon of the Obturator externus; *below*, it is continuous with the inferior ramus; in *front* it is limited by the posterior margin of the obturator foramen; *behind*, a prominent margin separates it from the posterior surface. In front of this margin the surface gives origin to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus; the lower part of the surface gives origin to part of the Adductor magnus. The **internal surface** forms part of the bony wall of the lesser pelvis. In *front* it is limited by the posterior margin of the obturator foramen. *Below*, it is bounded by a sharp ridge which gives attachment to a falciform prolongation of the sacrotuberous ligament, and, more anteriorly, gives origin to the Transversus perinaei and Ischiocavernosus. *Posteriorly* the ramus forms a large swelling, the **tuberosity of the ischium**, which is divided into two portions: a lower, rough, somewhat triangular part, and an upper, smooth, quadrilateral portion. The lower portion is subdivided by a prominent longitudinal ridge, passing from base to apex, into two parts; the outer gives attachment to the Adductor magnus, the inner to the sacrotuberous ligament. The upper portion is subdivided into two areas by an oblique ridge, which runs downward and outward; from the upper and outer area the Semimembranosus arises; from the lower and inner, the long head of the Biceps femoris and the Semitendinosus.

The Inferior Ramus (*ramus inferior oss. ischii; ascending ramus*).—The inferior ramus is the thin, flattened part of the ischium, which ascends from the superior ramus, and joins the inferior ramus of the pubis—the junction being indicated in the adult by a raised line. The **outer surface** is uneven for the origin of the Obturator externus and some of the fibres of the Adductor magnus; its **inner surface** forms part of the anterior wall of the pelvis. Its **medial border** is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the inferior ramus of the pubis: to the outer is attached the deep layer of the superficial perineal fascia (*fascia of Colles*), and to the inner the inferior fascia of the urogenital diaphragm. If these two ridges be traced downward, they will be found to join with each other just behind the point of origin of the Transversus perinaei; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, the Transversus perinaei is attached, and in front of this a portion of the crus penis vel clitoridis and the Ischiocavernosus. Its **lateral border** is thin and sharp, and forms part of the medial margin of the obturator foramen.

The Pubis (*os pubis*).—The pubis, the anterior part of the hip bone, is divisible into a **body**, a **superior** and an **inferior ramus**.

The Body (*corpus oss. pubis*).—The body forms one-fifth of the acetabulum, contributing by its **external surface** both to the lunate surface and the acetabular fossa. Its **internal surface** enters into the formation of the wall of the lesser pelvis and gives origin to a portion of the Obturator internus.

The Superior Ramus (*ramus superior oss. pubis; ascending ramus*).—The superior ramus extends from the body to the median plane where it articulates with its fellow of the opposite side. It is conveniently described in two portions,—viz., a medial flattened part and a narrow lateral prismoid portion.

The **Medial Portion** of the superior ramus, formerly described as the body of the pubis, is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The **anterior surface** is rough, directed downward and

outward, and serves for the origin of various muscles. The Adductor longus arises from the upper and medial angle, immediately below the crest; lower down, the Obturator externus, the Adductor brevis, and the upper part of the Gracilis take origin. The **posterior surface**, convex from above downward, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives origin to the Levator ani and Obturator internus, and attachment to the puboprostatic ligaments and to a few muscular fibres prolonged from the bladder. The **upper border** presents a prominent tubercle, the **pubic tubercle** (*pubic spine*), which projects forward; the inferior crus of the **subcutaneous inguinal ring** (*external abdominal ring*), and the **inguinal ligament** (*Poupart's ligament*) are attached to it. Passing upward and lateralward from the pubic tubercle is a well-defined ridge, forming a part of the pectineal line which marks the brim of the lesser pelvis: to it are attached a portion of the **inguinal falx** (*conjoined tendon of Obliquus internus and Transversus*), the **lacunar ligament** (*Gimbernat's ligament*), and the **reflected inguinal ligament** (*triangular fascia*). Medial to the pubic tubercle is the **crest**, which extends from this process to the medial end of the bone. It affords attachment to the inguinal falx, and to the Rectus abdominis and Pyramidalis. The point of junction of the crest with the medial border of the bone is called the **angle**; to it, as well as to the symphysis, the superior crus of the subcutaneous inguinal ring is attached. The **medial border** is articular; it is oval, and is marked by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, which intervenes between it and the interpubic fibrocartilaginous lamina. The **lateral border** presents a sharp margin, the **obturator crest**, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **Lateral Portion** of the ascending ramus has three surfaces: superior, inferior, and posterior. The **superior surface** presents a continuation of the pectineal line, already mentioned as commencing at the pubic tubercle. In front of this line, the surface of bone is triangular in form, wider laterally than medially, and is covered by the Pectineus. The surface is bounded, laterally, by a rough eminence, the **iliopectineal eminence**, which serves to indicate the point of junction of the ilium and pubis, and below by a prominent ridge which extends from the acetabular notch to the pubic tubercle. The **inferior surface** forms the upper boundary of the obturator foramen, and presents, laterally, a broad and deep, oblique groove, for the passage of the obturator vessels and nerve; and medially, a sharp margin, the **obturator crest**, forming part of the circumference of the obturator foramen, and giving attachment to the obturator membrane. The **posterior surface** constitutes part of the anterior boundary of the lesser pelvis. It is smooth, convex from above downward, and affords origin to some fibres of the Obturator internus.

The **Inferior Ramus** (*ramus inferior oss. pubis; descending ramus*).—The inferior ramus is thin and flattened. It passes lateralward and downward from the medial end of the superior ramus; it becomes narrower as it descends and joins with the inferior ramus of the ischium below the obturator foramen. Its **anterior surface** is rough, for the origin of muscles—the Gracilis along its medial border, a portion of the Obturator externus where it enters into the formation of the obturator foramen, and between these two, the Adductores brevis and magnus, the former being the more medial. The **posterior surface** is smooth, and gives origin to the Obturator internus, and, close to the medial margin, to the Constrictor urethrae. The **medial border** is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downward, and are continuous with similar ridges on the inferior ramus of the ischium; to the external is attached the fascia of Colles, and to the internal the inferior fascia of the urogenital diaphragm. The **lateral border** is thin and sharp, forms part of the

circumference of the obturator foramen, and gives attachment to the obturator membrane.

The Acetabulum (*cotyloid cavity*).—The acetabulum is a deep, cup-shaped, hemispherical depression, directed downward, lateralward, and forward. It is formed medially by the pubis, above by the ilium, laterally and below by the ischium; a little less than two-fifths is contributed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubis. It is bounded by a prominent uneven rim, which is thick and strong above, and serves for the attachment of the **glenoidal labrum** (*cotyloid ligament*), which contracts its orifice, and deepens the surface for articulation. It presents below a deep notch, the **acetabular notch**, which is continuous with a circular non-articular depression, the **acetabular fossa**, at the bottom of the cavity: this depression is perforated by numerous apertures, and lodges a mass of fat. The notch is converted into a foramen by the transverse ligament; through the foramen nutrient vessels and nerves enter the joint; the margins of the notch serve for the attachment of the **ligamentum teres**. The rest of the acetabulum is formed by a curved articular surface, the **lunate surface**, for articulation with the head of the femur.

By eight centres { Three primary (Ilium, Ischium, and Pubis)
Five secondary

C r e e k

FIG. 377.—Plan of ossification of the hip bone. The three primary centres unite through a Y-shaped piece about puberty. Epiphyses appear about puberty, and unite about twenty-fifth year.

The Obturator Foramen (*foramen obturatum; thyroid foramen*).—The obturator foramen is a large aperture, situated between the ischium and pubis. In the male it is large and of an oval form, its longest diameter slanting obliquely from before backward; in the female it is smaller, and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached, and presents, superiorly, a deep groove, the **obturator groove**, which runs from the pelvis obliquely medialward and downward. This groove is converted into a canal by a ligamentous band, a specialized part of the obturator membrane, attached to two tubercles: one, the **posterior obturator tubercle**, on the medial border of the ischium, just in front of the acetabular notch; the other, the **anterior obturator tubercle**, on the

obturator crest of the superior ramus of the pubis. Through the canal the obturator vessels and nerve pass out of the pelvis.

Structure.—The thicker parts of the bone consist of cancellous tissue, enclosed between two layers of compact tissue; the thinner parts, as at the bottom of the acetabulum and centre of the iliac fossa, are usually semitransparent, and composed entirely of compact tissue.

Ossification (Fig. 377).—The hip bone is ossified from *eight* centres: *three* primary—one each for the ilium, ischium, and pubis; and *five* secondary—one each for the crest of the ilium, the anterior inferior spine (said to occur more frequently in the male than in the female), the tuberosity of the ischium, the pubic symphysis (more frequent in the female than in the male), and one or more for the Y-shaped piece at the bottom of the acetabulum. The centres appear in the following order: in the lower part of the ilium, immediately above the greater sciatic notch, about the eighth or ninth week of fetal life; in the superior ramus of the ischium, about the third month; in the superior ramus of the pubis, between the fourth and fifth months. At birth, the three primary centres are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, and the inferior rami of the ischium and pubis being still cartilaginous. By the seventh or eighth year, the inferior rami of the pubis and ischium are almost completely united by bone. About the thirteenth or fourteenth year, the three primary centres have extended their growth into the bottom of the acetabulum, and are there separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the *os acetabuli*, appears about the age of twelve, between the ilium and pubis, and fuses with them about the age of eighteen; it forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the pubis and ischium, through the intervention of this Y-shaped portion. At about the age of puberty, ossification takes place in each of the remaining portions, and they join with the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic tubercle and the ischial spine, and for the crest and angle of the pubis.

Articulations.—The hip bone articulates with its fellow of the opposite side, and with the sacrum and femur.

The Pelvis.

The **pelvis**, so called from its resemblance to a basin, is a bony ring, interposed between the movable vertebræ of the vertebral column which it supports, and the lower limbs upon which it rests; it is stronger and more massively constructed than the wall of the cranial or thoracic cavities, and is composed of four bones: the two **hip bones** laterally and in front and the **sacrum** and **coccyx** behind.

The pelvis is divided by an oblique plane passing through the prominence of the sacrum, the arcuate and pectineal lines, and the upper margin of the symphysis pubis, into the greater and the lesser pelvis. The circumference of this plane is termed the **linea terminalis** or **pelvic brim**.

The Greater or False Pelvis (*pelvis major*).—The greater pelvis is the expanded portion of the cavity situated above and in front of the pelvic brim. It is bounded on either side by the ilium; in *front* it is incomplete, presenting a wide interval between the anterior borders of the ilia, which is filled up in the recent state by the parietes of the abdomen; behind is a deep notch on either side between the ilium and the base of the sacrum. It supports the intestines, and transmits part of their weight to the anterior wall of the abdomen.

The Lesser or True Pelvis (*pelvis minor*).—The lesser pelvis is that part of the pelvic cavity which is situated below and behind the pelvic brim. Its bony walls are more complete than those of the greater pelvis. For convenience of description, it is divided into an **inlet** bounded by the superior circumference, and **outlet** bounded by the inferior circumference, and a **cavity**.

The Superior Circumference.—The superior circumference forms the brim of the pelvis, the included space being called the **superior aperture** or **inlet** (*apertura pelvis [minoris] superior*) (Fig. 378). It is formed laterally by the pectineal and arcuate lines, in front by the crests of the pubes, and behind by the anterior margin of the base of the sacrum and sacrovertebral angle. The superior aperture is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forward of the promontory of the sacrum. It has

three principal diameters: antero-posterior, transverse, and oblique. The **antero-posterior** or **conjugate diameter** extends from the sacrovertebral angle to the symphysis pubis; its average measurement is about 110 mm. in the female. The **transverse diameter** extends across the greatest width of the superior aperture, from the middle of the brim on one side to the same point on the opposite; its average measurement is about 135 mm. in the female. The **oblique diameter** extends from the iliopectineal eminence of one side to the sacroiliac articulation of the opposite side; its average measurement is about 125 mm. in the female

FIG. 378.—Diameters of superior aperture of lesser pelvis (female)

The **cavity** of the lesser pelvis is bounded in front and below by the pubic symphysis and the superior rami of the pubes; above and behind, by the pelvic surfaces of the sacrum and coccyx, which, curving forward above and below, contract the superior and inferior apertures of the cavity; laterally, by a broad, smooth, quadrangular area of bone, corresponding to the inner surfaces of the body and superior ramus of the ischium and that part of the ilium which is below the arcuate line. From this description it will be seen that the cavity of the lesser pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall. It contains, in the recent subject, the pelvic colon, rectum, bladder, and some of the organs of generation. The rectum is placed at the back of the pelvis, in the curve of the sacrum and coccyx; the bladder is in front, behind the pubic symphysis. In the female, the uterus and vagina occupy the interval between these viscera.

The Lower Circumference.—The lower circumference of the pelvis is very irregular; the space enclosed by it is named the **inferior aperture** or **outlet** (*apertura pelvis [minoris] inferior*) (Fig. 379), and is bounded behind by the point of the coccyx, and laterally by the ischial tuberosities. These eminences are separated by three notches: one in front, the **pubic arch**, formed by the convergence of the inferior rami of the ischium and pubis on either side. The other notches, one on either side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above; they are called the **sciatic notches**; in the natural state they are converted into foramina by the sacrotuberous and sacrospinous ligaments. When the ligaments are *in situ*, the inferior aperture of the pelvis is lozenge-shaped, bounded, in front, by the pubic arcuate ligament and the inferior rami of the pubes and ischia; laterally, by the ischial tuberosities; and behind, by the sacrotuberous ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The **antero-posterior diameter** extends from the tip of the coccyx to the lower part of the pubic symphysis; its measurement is from 90 to 115 mm. in the female. It varies with the length of the coccyx, and is capable of increase or diminution, on account of the mobility of that bone. The **transverse diameter**, measured between the posterior parts of the ischial tuberosities, is about 115 mm. in the female.¹

FIG. 379.—Diameters of inferior aperture of lesser pelvis (female).

Axes (Fig. 380).—A line at right angles to the plane of the superior aperture at its centre would, if prolonged, pass through the umbilicus above and the middle of the coccyx below; the axis of the superior aperture is therefore directed downward and backward. The axis of the inferior aperture, produced upward, would touch the base of the sacrum, and is also directed downward, and slightly backward. The axis of the cavity—*i. e.*, an axis at right angles to a series of planes between those of the superior and inferior apertures—is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the superior and inferior apertures. A knowledge of the direction of these axes serves to explain the course of the fetus in its passage through the pelvis during parturition.

FIG. 380.—Median sagittal section of pelvis.

Position of the Pelvis (Fig. 380).—In the erect posture, the pelvis is placed obliquely with regard to the trunk: the plane of the superior aperture forms an angle of from 50° to 60° , and that of the inferior aperture one of about 15° with the horizontal plane. The pelvic surface of the symphysis pubis looks upward and backward, the concavity of the sacrum and coccyx downward and forward. The position of the pelvis in the erect posture may be indicated by holding it so that the anterior superior iliac spines and the front of the top of the symphysis pubis are in the same vertical plane.

¹ The measurements of the pelvis given above are fairly accurate, but different figures are given by various authors no doubt due mainly to differences in the physique and stature of the population from whom the measurements have been taken.

Differences between the Male and Female Pelves.—The *female* pelvis (Fig. 382) is distinguished from that of the *male* (Fig. 381) by its bones being more delicate and its depth less. The whole pelvis is less massive, and its muscular

FIG. 381.—Male pelvis.

impressions are slightly marked. The ilia are less sloped, and the anterior iliac spines more widely separated; hence the greater lateral prominence of the hips. The preauricular sulcus is more commonly present and better marked. The supe-

FIG. 382.—Female pelvis.

rior aperture of the lesser pelvis is larger in the female than in the male; it is more nearly circular, and its obliquity is greater. The cavity is shallower and wider; the sacrum is shorter, wider, and its upper part is less curved; the obturator

foramina are triangular in shape and smaller in size than in the male. The inferior aperture is larger and the coccyx more movable. The sciatic notches are wider and shallower, and the spines of the ischia project less inward. The acetabula are smaller and look more distinctly forward (Derry¹). The ischial tuberosities and the acetabula are wider apart, and the former are more everted. The pubic symphysis is less deep, and the pubic arch is wider and more rounded than in the male, where it is an angle rather than an arch.

The size of the pelvis varies not only in the two sexes, but also in different members of the same sex, and does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelvis. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure 12.5 mm. less than the average, and this even in well-formed women of average height. The principal divergences, however, are found at the superior aperture, and affect the relation of the antero-posterior to the transverse diameter. Thus the superior aperture may be elliptical either in a transverse or an antero-posterior direction, the transverse diameter in the former, and the antero-posterior in the latter, greatly exceeding the other diameters; in other instances it is almost circular.

In the foetus, and for several years after birth, the pelvis is small in proportion to that of the adult, and the projection of the sacrovertebral angle less marked. The characteristic differences between the male and female pelvis are distinctly indicated as early as the fourth month of fetal life.

Applied Anatomy.—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle is deficient, the superior rami of the pubes are imperfectly developed, and the symphysis is absent. "The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forward, and the obturator foramen diminished in size, narrowed, and turned outward. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the iliosacral facets turned more outward than normal, while the vertical curve is straightened."²

Fractures of the pelvis are divided into those of the greater and those of the lesser pelvis. Fractures of the greater pelvis vary in extent; a small portion of the crest may be broken, or one of the spinous processes may be torn off, or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the lesser pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the lesser pelvis. A fracture of the lesser pelvis generally occurs through the superior ramus of the pubis and the inferior ramus of the ischium, as these are the weakest parts of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together and the bone gives way in the same place from indirect violence. Sometimes both sides of the pelvis are fractured, and it is in these cases that the contained viscera are likely to be injured: the urethra, the bladder, the rectum, the small intestines, the vagina, and even the uterus, have all been lacerated by displaced fragments. Fractures of the acetabulum are occasionally met with; either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur be driven into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, splitting the bone into its three portions.

The coccyx is not infrequently displaced forward to nearly a right angle with the sacrum by a kick or by a fall backward. The condition is attended with great pain in walking and on making any expiratory effort, such as coughing, defecation, etc., because the Coccygei and Levatores ani which form the pelvic diaphragm are attached to this bone. Such injuries often give rise to severe persistent pain, which is exceedingly intractable and difficult of cure. The condition is known as *coccygodynia* and for its relief removal of the coccyx has been practised.

The pelvic bones often undergo important deformity in *rickets*, the effects of which in the adult woman may interfere seriously with child-bearing. The deformity is due mainly to the weight of the trunk, which presses on the sacrovertebral angle and greatly increases it, so that the antero-posterior diameter of the pelvis is diminished, and may measure as little as 40 mm.,

¹ Journal of Anatomy and Physiology, vol. xliii.

² Wood, Heath's Dictionary of Practical Surgery, i, 426.

the entrance into the pelvis becoming reniform. In other cases all the pelvic bones give way, so that a general diminution in all the diameters of the pelvis results, the pelvic entrance becoming triangular or asymmetrical. If the pubic symphysis be forced forward, the rickety pelvis may even come to resemble closely the deformed pelvis of *osteomalacia*; in this disease the weight of the trunk causes an increase in the sacrovertebral angle, and a lessening of the antero-posterior diameter of the superior aperture, and at the same time the pressure of the heads of the femora on the acetabula causes these cavities, with the adjacent bone, to be pushed upward and backward, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a triradiate shape, with the symphysis pubis pushed forward.

The Femur (Thigh Bone).

The femur (Figs. 384, 385), the longest and strongest bone in the skeleton, is almost perfectly cylindrical in the greater part of its extent. In the erect posture it is not vertical, being separated above from its fellow by a considerable interval, which corresponds to the breadth of the pelvis, but inclining gradually downward and medialward, so as to approach its fellow toward its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than in the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a **body** and **two extremities**.

*tion of Obturator
externus*

*Fovea capitis,
for lig. teres*

Greater trochanter

L

FIG. 383.—Upper extremity of right femur viewed from behind and above.

The Upper Extremity (*proximal extremity*, Fig. 383).—The upper extremity presents for examination a **head**, a **neck**, a **greater** and a **lesser trochanter**.

The Head (*caput femoris*).—The head which is globular and forms rather more than a hemisphere, is directed upward, medialward, and a little forward, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the recent state, except over an ovoid depression, the **fovea capitis femoris**, which is situated a little below and behind the centre of the head, and gives attachment to the ligamentum teres.

The Neck (*collum femoris*).—The neck is a flattened pyramidal process of bone, connecting the head with the body, and forming with the latter a wide angle opening medialward. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the body of the bone. In the adult, the neck forms an angle of about 125° with the body, but this varies in inverse proportion to the development of the pelvis and the stature. In

Obturator internus

I

Fovea capitis

ericle

r capule

the female, in consequence of the increased width of the pelvis, the neck of the femur forms more nearly a right angle with the body than it does in the male. The angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age; it varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide. In addition to projecting upward and medialward from the body of the femur, the neck also projects somewhat forward; the amount of this forward projection is extremely variable, but on an average is from 12° to 14°.

The neck is flattened from before backward, contracted in the middle, and broader laterally than medially. The vertical diameter of the lateral half is increased by the obliquity of the lower edge, which slopes downward to join the body at the level of the lesser trochanter, so that it measures one-third more than the antero-posterior diameter. The medial half is smaller and of a more circular shape. The **anterior surface** of the neck is perforated by numerous vascular foramina. Along the upper part of the line of junction of the anterior surface with the head is a shallow groove, best marked in elderly subjects; this groove lodges the orbicular fibres of the capsule of the hip-joint. The **posterior surface** is smooth, and is broader and more concave than the anterior: the posterior part of the capsule of the hip-joint is attached to it about 1 cm. above the intertrochanteric crest. The **superior border** is short and thick, and ends laterally at the greater trochanter; its surface is perforated by large foramina. The **inferior border**, long and narrow, curves a little backward, to end at the lesser trochanter.

The Trochanters.—The trochanters are prominent processes which

Lateral epicondyle

r capule

Adductor tubercle

Medial epicondyle

FIG. 384.—Right femur. Anterior surface.

afford leverage to the muscles that rotate the thigh on its axis. They are two in number, the greater and the lesser.

The **Greater Trochanter** (*trochanter major; great trochanter*) is a large, irregular, quadrilateral eminence, situated at the junction of the neck with the upper part of the body. It is directed a little lateralward and backward, and, in the adult, is about 1 cm. lower than the head. It has two surfaces and four borders. The **lateral surface**, quadrilateral in form, is broad, rough, convex, and marked by a diagonal impression, which extends from the postero-superior to the antero-inferior angle, and serves for the insertion of the tendon of the *Glutaeus medius*. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between the tendon and the bone. Below and behind the diagonal impression is a smooth, triangular surface, over which the tendon of the *Glutaeus maximus* plays, a bursa being interposed. The **medial surface**, of much less extent than the lateral, presents at its base a deep depression, the **trochanteric fossa** (*digital fossa*), for the insertion of the tendon of the *Obturator externus*, and above and in front of this an impression for the insertion of the *Obturator internus* and *Gemelli*. The **superior border** is free; it is thick and irregular, and marked near the centre by an impression for the insertion of the *Piriformis*. The **inferior border** corresponds to the line of junction of the base of the trochanter with the lateral surface of the body; it is marked by a rough, prominent, slightly curved ridge, which gives origin to the upper part of the *Vastus lateralis*. The **anterior border** is prominent and some-

FIG. 385.—Right femur. Posterior surface

what irregular; it affords insertion at its lateral part to the *Glutaeus minimus*. The **posterior border** is very prominent and appears as a free, rounded edge, which bounds the back part of the trochanteric fossa.

The **Lesser Trochanter** (*trochanter minor*; *small trochanter*) is a conical eminence, which varies in size in different subjects; it projects from the lower and back part of the base of the neck. From its apex three well-marked borders extend; two of these are above—a **medial** continuous with the lower border of the neck, a **lateral** with the intertrochanteric crest; the **inferior border** is continuous with the middle division of the *linea aspera*. The **summit** of the trochanter is rough, and gives insertion to the tendon of the *Psoas major*.

A prominence, of variable size, occurs at the junction of the upper part of the neck with the greater trochanter, and is called the **tubercle of the femur**; it is the point of meeting of five muscles: the *Glutaeus minimus* laterally, the *Vastus lateralis* below, and the tendon of the *Obturator internus* and two *Gemelli* above. Running obliquely downward and medialward from the tubercle is the **intertrochanteric line** (*spiral line of the femur*); it winds around the medial side of the body of the bone, below the lesser trochanter, and ends about 5 cm. below this eminence in the *linea aspera*. Its upper half is rough, and affords attachment to the ilio-femoral ligament of the hip-joint; its lower half is less prominent, and gives origin to the upper part of the *Vastus medialis*. Running obliquely downward and medialward from the summit of the greater trochanter on the posterior surface of the neck is a prominent ridge, the **intertrochanteric crest**. Its upper half forms the posterior border of the greater trochanter, and its lower half runs downward and medialward to the lesser trochanter. A slight ridge is sometimes seen commencing about the middle of the intertrochanteric crest, and reaching vertically downward for about 5 cm. along the back part of the body: it is called the ***linea quadrata***, and gives attachment to the *Quadratus femoris* and a few fibres of the *Adductor magnus*. Generally there is merely a slight thickening about the middle of the intertrochanteric crest, marking the attachment of the upper part of the *Quadratus femoris*.

The Body or Shaft (*corpus femoris*).—The body, almost cylindrical in form, is a little broader above than in the centre, broadest and somewhat flattened from before backward below. It is slightly arched, so as to be convex in front, and concave behind, where it is strengthened by a prominent longitudinal ridge, the ***linea aspera***. It presents for examination three borders, separating three surfaces. Of the three borders, one, the *linea aspera*, is posterior, one is medial, and the other, lateral.

The ***linea aspera*** (Fig. 385) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting a medial and a lateral lip, and a narrow rough, intermediate line. Above, the *linea aspera* is prolonged by three ridges. The lateral ridge is very rough, and runs almost vertically upward to the base of the greater trochanter. It is termed the **gluteal tuberosity**, and gives attachment to part of the *Glutaeus maximus*: its upper part is often elongated into a roughened crest, on which a more or less well-marked, rounded tubercle, the **third trochanter**, is occasionally developed. The intermediate ridge or **pectineal line** is continued to the base of the lesser trochanter and gives attachment to the *Pectineus*; the medial ridge is lost in the intertrochanteric line; between these two a portion of the *Iliacus* is inserted. Below, the *linea aspera* is prolonged into two ridges, enclosing between them a triangular area, the **popliteal surface**, upon which the popliteal artery rests. Of these two ridges, the lateral is the more prominent, and descends to the summit of the lateral condyle. The medial is less marked, especially at its upper part, where it is crossed by the femoral artery. It ends below at the summit of the medial condyle, in a small tubercle, the **adductor tubercle**, which affords insertion to the tendon of the *Adductor magnus*.

From the **medial lip** of the *linea aspera* and its prolongations above and below, the *Vastus medialis* arises; and from the **lateral lip** and its upward prolongation, the *Vastus lateralis* takes origin. The *Adductor magnus* is inserted into the *linea aspera*, and to its lateral prolongation above, and its medial prolongation below. Between the *Vastus lateralis* and the *Adductor magnus* two muscles are attached—viz., the *Gluteus maximus* inserted above, and the short head of the *Biceps femoris* arising below. Between the *Adductor magnus* and the *Vastus medialis* four muscles are inserted: the *Iliacus* and *Pectineus* above; the *Adductor brevis* and *Adductor longus* below. The *linea aspera* is perforated a little below its centre by the nutrient canal, which is directed obliquely upward.

The other two borders of the femur are only slightly marked: the **lateral border** extends from the antero-inferior angle of the greater trochanter to the anterior extremity of the lateral condyle; the **medial border** from the intertrochanteric line, at a point opposite the lesser trochanter, to the anterior extremity of the medial condyle.

The **anterior surface** includes that portion of the shaft which is situated between the lateral and medial borders. It is smooth, convex, broader above and below than in the centre. From the upper three-fourths of this surface the *Vastus intermedius* arises; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa; from the upper part of it the *Articularis genu* takes origin. The **lateral surface** includes the portion between the lateral border and the *linea aspera*; it is continuous above with the corresponding surface of the greater trochanter, below with that of the lateral condyle: from its upper three-fourths the *Vastus intermedius* takes origin. The **medial surface** includes the portion between the medial border and the *linea aspera*; it is continuous above with the lower border of the neck, below with the medial side of the medial condyle: it is covered by the *Vastus medialis*.

FIG. 386.—Lower extremity of right femur viewed from below.

The Lower Extremity (*distal extremity*, Fig. 386).—The lower extremity, larger than the upper, is somewhat cuboid in form, but its transverse diameter is greater than its antero-posterior; it consists of two oblong eminences known as the **condyles**. In front, the condyles are but slightly prominent, and are separated from one another by a smooth shallow articular depression called the **patellar surface**; behind, they project considerably, and the interval between them forms a deep notch, the **intercondyloid fossa**. The **lateral condyle** is the more prominent and is the broader both in its antero-posterior and transverse diameters, the **medial condyle** is the longer and, when the femur is held with its body perpendicular, projects to a lower level. When, however, the femur is in its natural oblique position the lower surfaces of the two condyles lie practically in the same horizontal plane. The condyles are not quite parallel with one another; the long axis of the lateral is almost

directly antero-posterior, but that of the medial runs backward and medialward. Their opposed surfaces are small, rough, and concave, and form the walls of the intercondyloid fossa. This fossa is limited above by a ridge, the **intercondyloid line**, and below by the central part of the posterior margin of the patellar surface. The posterior cruciate ligament of the knee-joint is attached to the lower and front part of the medial wall of the fossa and the anterior cruciate ligament to an impression on the upper and back part of its lateral wall. Each condyle is surmounted by an elevation, the epicondyle. The **medial epicondyle** is a large convex eminence to which the tibial collateral ligament of the knee-joint is attached. At its upper part is the adductor tubercle, already referred to, and behind it is a rough impression which gives origin to the medial head of the Gastrocnemius. The **lateral epicondyle**, smaller and less prominent than the medial, gives attachment to the fibular collateral ligament of the knee-joint. Directly below it is a small depression from which a smooth well-marked groove curves obliquely upward and backward to the posterior extremity of the condyle. This groove is separated from the articular surface of the condyle by a prominent lip across which a second, shallower groove runs vertically downward from the depression. In the recent state these grooves are covered with cartilage. The Popliteus arises from the depression; its tendon lies in the oblique groove when the knee is flexed and in the vertical groove when the knee is extended. Above and behind the lateral epicondyle is an area for the origin of the lateral head of the Gastrocnemius, above and to the medial side of which the Plantaris arises.

The **articular surface** of the lower end of the femur occupies the anterior, inferior, and posterior surfaces of the condyles. Its front part is named the **patellar surface** and articulates with the patella; it presents a median groove which extends downward to the intercondyloid fossa and two convexities, the lateral of which is broader, more prominent, and extends farther upward than the medial. The lower and posterior parts of the articular surface constitute the **tibial surfaces** for articulation with the corresponding condyles of the tibia and menisci. These surfaces are separated from one another by the intercondyloid fossa and from the patellar surface by faint grooves which extend obliquely across the condyles. The lateral groove is the better marked; it runs lateralward and forward from the front part of the intercondyloid fossa, and expands to form a triangular depression. When the knee-joint is fully extended, the triangular depression rests upon the anterior portion of the lateral meniscus, and the medial part of the groove comes into contact with the medial margin of the lateral articular surface of the tibia in front of the lateral tubercle of the tibial intercondyloid eminence. The medial groove is less distinct than the lateral. It does not reach as far as the intercondyloid fossa and therefore exists only on the medial part of the condyle; it receives the anterior edge of the medial meniscus when the knee-joint is extended. Where the groove ceases laterally the patellar surface is seen to be continued backward as a semilunar area close to the anterior part of the intercondyloid fossa; this semilunar area articulates with the medial vertical facet of the patella in forced flexion of the knee-joint. The tibial surfaces of the condyles are convex from side to side and from before backward. Each presents a double curve, its posterior segment being an arc of a circle, its anterior, part of a cycloid.¹

Structure.—The body of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The wall of the cylinder is of great thickness and density in the middle third of the body, where the bone is narrowest and the medullary canal best formed; but above and below this the wall becomes thinner, while the medullary canal is gradually filled up by cancellous tissue, so that the upper (Fig. 387) and lower ends of the body, and the articular extremities more especially, consist of cancellous tissue, invested by a thin compact layer.

¹ A *cycloid* is a curve traced by a point in the circumference of a wheel when the wheel is rolled along in a straight line.

The cancelli in the ends of the femur are disposed along the lines of greatest pressure and tension. In the upper end (Fig. 388) the chief lamellæ are arranged in the following manner. A series of bony planes at right angles to the articular surface of the head converge to a central

FIG. 387.—Longitudinal section of head and neck of femur.

dense wedge, which presents few and dense cancelli. The wedge is supported by strong lamellæ, which extend to the sides of the neck and are especially marked along its upper and lower borders. Any force therefore applied to the head of the femur is transmitted directly to the central wedge and thence to the junction of the neck with the body. This junction is especially strengthened by a series of dense lamellæ which extend from the lesser trochanter to the lateral end of the superior border of the neck; this arrangement will obviously oppose considerable resistance to either tensile or shearing force. A smaller bar stretching across the junction of the greater trochanter with the neck and body resists the shearing force of the muscles attached to this prominence. These two bars, one at the junction of body and neck, the other at the junction of body and greater trochanter, form the upper layers of a series of arches which extend across between the sides of the body and transmit to the body forces applied to the upper end of the bone. In the cancellous tissue of the neck is a thin vertical plate of bone, the *calcar femorale*, which springs from the compact wall of the body in the region of the *linea aspera*. Medially it is attached to the interior surface of the posterior wall of the neck of the bone; laterally it continues the plane of the posterior wall of the neck into the greater trochanter where it shades off into the general cancellous tissue. It is thus situated in a plane anterior to the intertrochanteric crest and to the base of the lesser trochanter (Fig. 389).

FIG. 388.—Scheme showing disposition of principal cancellous lamellæ in upper extremity of femur.

In the lower end, the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, there

are horizontal planes of cancellous tissue, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of cubical areas.

Articulations.—The femur articulates with *three* bones: the hip bone, tibia, and patella.

Ossification (Figs. 390, 391, 392).—The femur is ossified from *five* centres: one for the body, one for the head, one for each trochanter, and one for the lower extremity. Of all the long bones, except the clavicle, it is the first to show traces of ossification; this commences in the middle of the body, at about the seventh week of fetal life, and rapidly extends upward and downward. The centres in the epiphyses appear in the following order: in the lower end of the bone, at the ninth month of fetal life (from this centre the condyles and epicondyles are formed); in the head, at the end of the first year after birth; in the greater trochanter, during the fourth year; and in the lesser trochanter, between the thirteenth and fourteenth years. The order in which the epiphyses are joined to the body is the reverse of that of their appearance; they are not united until after puberty, the lesser trochanter being first joined, then the greater, then the head, and, lastly, the inferior extremity, which is not united until the twentieth year.

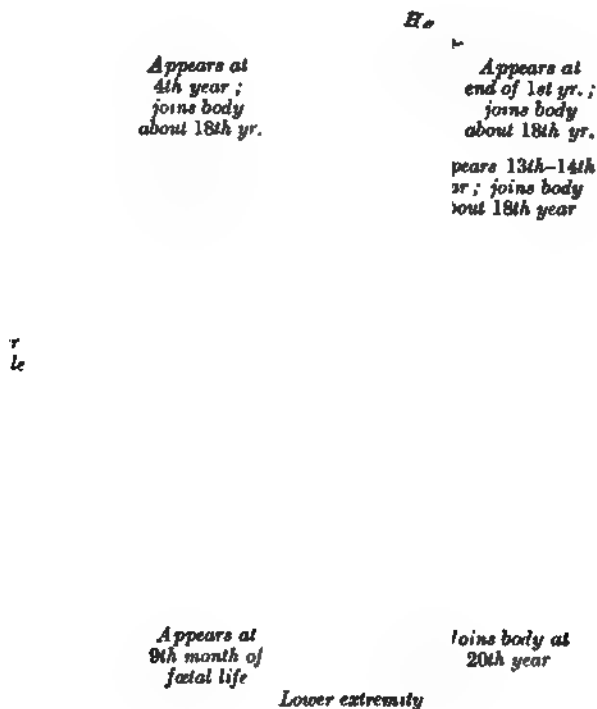

FIG. 389.—Oblique section of upper extremity of femur showing calcar femorale

FIG. 390.—Plan of ossification of the femur. From five centres

Applied Anatomy.—The lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of this ossific centre is, therefore, a proof, in a newly born child found dead, that the child has arrived at the full period of uterogestation, and is always relied upon in medicolegal investigations. The position of the epiphysal plate should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysal cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render the limb almost useless. Separation of the lower epiphysis may take place up to the age

of twenty, at which time it becomes completely joined to the body of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is the seat of origin, in a large number of cases, of tuberculous disease of the hip-joint. In the majority of cases the disease begins in the highly vascular and growing tissue at the end of the body in the neighborhood of the epiphysial cartilage, and extends into the joint. The epiphysis for the head is entirely intracapsular.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the body; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the greater trochanter; (3) fracture of the greater trochanter; and (4) separation of the epiphysis, either of the head or of the greater trochanter. The first of these, fracture of the neck, is usually termed *intracapsular* fracture, but this is scarcely a correct designation, as, owing to the attachment of the articular capsule, the fracture is partly within and partly without the capsule when the fracture occurs at the lower part of the neck. It generally takes place in old people, principally women, and

FIG. 391.—Epiphysial lines of femur in a young adult. Anterior aspect. The lines of attachment of the articular capsules are in blue.

FIG. 392.—Epiphysial lines of femur in a young adult. Posterior aspect. The lines of attachment of the articular capsules are in blue.

usually from a very slight degree of indirect violence. Probably the main cause of its occurrence in old people is the senile degenerative change which takes place in the bone. Merkel believes that it is mainly due to the absorption of the *calcar femorale*. As a rule the fragments become united by fibrous tissue, but frequently no union takes place, and the opposed surfaces become smooth and eburnated.

Fractures at the junction of the neck with the greater trochanter are usually termed *extra-capsular*, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the greater trochanter, as from a fall laterally on the hip. From the manner in which the accident is caused the neck of the bone is driven into the trochanter, where it may remain impacted, or the trochanter may be split into two or more fragments, disimpaction resulting.

Fractures of the body may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence. Fractures of the upper third of the body are almost always the result of indirect violence, while those of the lower third

are the result, for the most part, of direct violence. Fractures of the body are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture separating either the medial or lateral condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur as well as the other bones of the leg is frequently the seat of acute osteomyelitis in children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Necrosis of portions of the diaphysis frequently ensues, especially in the region of the popliteal surface of the femur, and the disease may continue for years, great trouble being experienced with discharging sinuses which periodically close and reopen to allow of the exit of a piece of dead bone.

Tumors are not infrequently found growing from the femur: the most common forms being sarcoma which may grow either from the periosteum or from the medullary tissue within the interior of the bone, and exostosis which commonly originates in the neighborhood of the epiphysal cartilage of the lower end. The periosteal sarcomata of the femur and most of the central growths are usually of a very high degree of malignancy, although the "myeloid" growth, which is of but low malignancy, may also be found. The region of the lower epiphysal line is by far the commoner seat for all these tumors, and it should be noted that the lower epiphysis has the longest period of active growth, and that these tumors usually appear toward the end of the period of active growth of the bone.

Sarcomata about the upper end of the femur are seen occasionally, but very rarely in comparison with those at the lower end. Secondary carcinoma also occurs in this bone, most commonly due to a primary focus in the breast, and spontaneous fracture of the bone may take place in these cases.

The Patella (Knee Cap).

The **patella** (Figs. 393, 394) is a flat, triangular bone, situated on the front of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps femoris, and resembles these bones (1) in being developed in a tendon; (2) in its centre of ossification presenting a knotty or tuberculated outline; (3) in being composed mainly of dense cancellous tissue. It serves to protect the front of the joint, and increases the leverage of the Quadriceps femoris by making it act at a greater angle. It has an anterior and a posterior surface three borders, and an apex.

FIG. 393.—Right patella.
Anterior surface.

FIG. 394.—Right patella.
Posterior surface.

Surfaces.—The **anterior surface** is convex, perforated by small apertures for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps femoris, which is continuous below with the superficial fibres of the ligamentum patellæ. It is separated from the integument by a bursa. The **posterior surface** presents above a smooth, oval, articular area, divided into two facets by a vertical ridge; the ridge corresponds to the groove on the patellar surface of the femur, and the facets to the medial and lateral parts of the same surface; the lateral facet is the broader and deeper. Below the articular surface is a rough, convex, non-articular area, the lower half of which gives attachment to the ligamentum patellæ; the upper half is separated from the head of the tibia by adipose tissue.

Borders.—The **base** or **superior border** is thick, and sloped from behind, downward, and forward; it gives attachment to that portion of the Quadriceps femoris which is derived from the Rectus femoris and Vastus intermedius. The **medial** and **lateral borders** are thinner and converge below: they give attachment to those

portions of the Quadriceps femoris which are derived from the Vasti lateralis and medialis.

Apex.—The apex is pointed, and gives attachment to the ligamentum patellae.

Structure.—The patella consists of a nearly uniform dense cancellous tissue, covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the articular surface toward the other parts of the bone.

Ossification.—The patella is ossified from a single centre, which usually makes its appearance in the second or third year, but may be delayed until the sixth year. More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulation.—The patella articulates with the femur.

Applied Anatomy.—The main surgical interest about the patella is in connection with fractures, which are of frequent occurrence. They are most often produced by muscular action—that is to say, by violent contraction of the quadriceps femoris while the limb is in a position of semi-flexion, so that the bone is snapped across the condyles of the femur and the fracture is transverse. Fracture of the patella is also produced by direct violence, such as falls on the knee, and here the fracture is usually stellate and the bone comminuted. Owing to the displacement of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue which may subsequently stretch, producing wide separation of the fragments and permanent lameness. Truly satisfactory results after this fracture are generally only to be obtained by opening the joint and wiring the fragments together, and this is especially so when there is marked separation of the fragments owing to laceration of the retinacula.

It is an anatomical possibility, if the fracture involve only the lower and non-articular part of the bone, for this to take place without injury to the synovial membrane and without involving the cavity of the knee-joint.

The Tibia (Shin Bone).

The tibia (Figs. 396, 397) is situated at the medial side of the leg, and, excepting the femur, is the longest bone of the skeleton. It is prismoid in form, expanded above, where it enters into the knee-joint, contracted in the lower third, and again enlarged but to a lesser extent below. In the male, its direction is vertical, and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downward and lateralward, to compensate for the greater obliquity of the femur. It has a **body** and **two extremities**.

The Upper Extremity (proximal extremity).

—The upper extremity is large, and expanded into two eminences, the **medial** and **lateral condyles**. The **superior articular surface** presents two smooth articular facets (Fig. 395). The medial facet, oval in shape, is slightly concave from side to side, and from before backward. The lateral, nearly circular, is

concave from side to side, but slightly convex from before backward, especially at its posterior part, where it is prolonged on to the posterior surface for a short distance. The central portions of these facets articulate with the condyles of the femur, while their peripheral portions support the menisci of the knee-joint, which here intervene between the two bones. Between the articular facets, but nearer the posterior than the anterior aspect of the bone, is the **intercondyloid eminence (spine of tibia)**, surmounted on either side by a prominent tubercle, on to the sides of which the articular facets are prolonged; in front of and behind the intercondyloid eminence are rough depressions for the attachment of the anterior and posterior cruciate ligaments and the menisci. The **anterior surfaces** of the condyles are continuous with one another, forming a large somewhat

Tuberosity

Intercondyloid eminence

FIG. 395.—Upper surface of right tibia.

*Articular capsule**Styl*

flattened area; this area is triangular, broad above, and perforated by large vascular foramina; narrow below where it ends in a large oblong elevation, the **tuberosity of the tibia**, which gives attachment to the ligamentum patellae; a bursa intervenes between the deep surface of the ligament and the part of the bone immediately above the tuberosity. *Posteriorly*, the condyles are separated from each other by a shallow depression, the **posterior intercondyloid fossa**, which gives attachment to part of the posterior cruciate ligament of the knee-joint. The **medial condyle** presents posteriorly a deep transverse groove, for the insertion of the tendon of the Semimembranosus. Its *medial surface* is convex, rough, and prominent; it gives attachment to the tibial collateral ligament. The **lateral condyle** presents posteriorly a flat articular facet, nearly circular in form, directed downward, backward, and lateralward, for articulation with the head of the fibula. Its *lateral surface* is convex, rough, and prominent in front: on it is an eminence, situated on a level with the upper border of the tuberosity and at the junction of its anterior and lateral surfaces, for the attachment of the iliotibial band. Just below this a part of the Extensor digitorum longus takes origin and a slip from the tendon of the Biceps femoris is inserted.

The Body or Shaft (*corpus tibiae*).

—The body has three borders and three surfaces.

Borders.—The **anterior crest or border**, the most prominent of the three, commences above at the tuberosity, and ends below at the anterior margin of the medial malleolus. It is sinuous and prominent in the upper two-thirds of its extent, but smooth and rounded below; it gives attachment to the deep fascia of the leg.

*Mus**Lateral malleolus*

FIG. 396.—Bones of the right leg Anterior surface.

The **medial border** is smooth and rounded above and below, but more prominent in the centre; it begins at the back part of the medial condyle, and ends at the posterior border of the medial malleolus; its upper part gives attachment to the tibial collateral ligament of the knee-joint to the extent of about 5 cm., and insertion to some fibres of the Popliteus; from its middle third some fibres of the Soleus and Flexor digitorum longus take origin.

*Articular
capsule*

*Articular
capsule
Styloid
process*

The **interosseous crest or lateral border** is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

Surfaces.—The **medial surface** is smooth, convex, and broader above than below; its upper third, directed forward and medialward, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forward as the anterior crest; in the rest of its extent it is subcutaneous.

The **lateral surface** is narrower than the medial; its upper two-thirds present a shallow groove for the origin of the Tibialis anterior; its lower third is smooth, convex, curves gradually forward to the anterior aspect of the bone, and is covered by the tendons of the Tibialis anterior, Extensor hallucis longus, and Extensor digitorum longus, arranged in this order from the medial side.

The **posterior surface** (Fig. 397) presents, at its upper part, a prominent ridge, the **popliteal line**, which extends obliquely downward from the back part of

FIGULA

Articular capsule

FIG. 397.—Bones of the right leg. Posterior surface.

the articular facet for the fibula to the medial border, at the junction of its upper and middle thirds; it marks the lower limit of the insertion of the Popliteus, serves for the attachment of the fascia covering this muscle, and gives origin to part of the Soleus, Flexor digitorum longus, and Tibialis posterior. The triangular area, above this line, gives insertion to the Popliteus. The middle third of the posterior surface is divided by a vertical ridge into two parts; the ridge begins at the popliteal line and is well-marked above, but indistinct below; the medial and broader portion gives origin to the Flexor digitorum longus, the lateral and narrower to part of the Tibialis posterior. The remaining part of the posterior surface is smooth and covered by the Tibialis posterior, Flexor digitorum longus, and Flexor hallucis longus. Immediately below the popliteal line is the **nutrient foramen**, which is large and directed obliquely downward.

The Lower Extremity (*distal extremity*).—The lower extremity, much smaller than the upper, presents five surfaces; it is prolonged downward on its medial side as a strong process, the **medial malleolus**.

Surfaces.—The **inferior articular surface** is quadrilateral, and smooth for articulation with the talus. It is concave from before backward, broader in front than behind, and traversed from before backward by a slight elevation, separating two depressions. It is continuous with that on the medial malleolus.

Lower extremity

FIG. 398.—Plan of ossification of the tibia. From three centres.

FIG. 399.—Epiphyseal lines of tibia and fibula in a young adult. Anterior aspect.

The **anterior surface** of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles; its lower margin presents a rough transverse depression for the attachment of the articular capsule of the ankle-joint.

The **posterior surface** is traversed by a shallow groove directed obliquely downward and medialward, continuous with a similar groove on the posterior surface of the talus and serving for the passage of the tendon of the Flexor hallucis longus.

The **lateral surface** presents a triangular rough depression for the attachment of the inferior interosseous ligament connecting it with the fibula; the lower part

of this depression is smooth, covered with cartilage in the recent state, and articulates with the fibula. The surface is bounded by two prominent borders, continuous above with the interosseous crest; they afford attachment to the anterior and posterior ligaments of the lateral malleolus.

The **medial surface** is prolonged downward to form a strong pyramidal process, flattened from without inward—the **medial malleolus**. The *medial surface* of this process is convex and subcutaneous; its *lateral or articular surface* is smooth and slightly concave, and articulates with the talus; its *anterior border* is rough, for the attachment of the anterior fibres of the deltoid ligament of the ankle-joint; its *posterior border* presents a broad groove, the **malleolar sulcus**, directed obliquely downward and medialward, and occasionally double; this sulcus lodges the tendons of the Tibialis posterior and Flexor digitorum longus. The *summit* of the medial malleolus is marked by a rough depression behind, for the attachment of the deltoid ligament.

Structure.—The structure of the tibia is like that of the other long bones. The compact wall of the body is thickest at the junction of the middle and lower thirds of the bone.

Ossification.—The tibia is ossified from *three* centres (Figs. 398, 399): one for the body and one for either extremity. Ossification begins in the centre of the body, about the seventh week of fetal life, and gradually extends toward the extremities. The centre for the upper epiphysis appears before or shortly after birth; it is flattened in form, and has a thin tongue-shaped process in front, which forms the tuberosity (Fig. 399); that for the lower epiphysis appears in the second year. The lower epiphysis joins the body at about the eighteenth, and the upper one joins about the twentieth year. Two additional centres occasionally exist, one for the tongue-shaped process of the upper epiphysis, which forms the tuberosity, and one for the medial malleolus.

Articulations.—The tibia articulates with three bones: the femur, fibula, and talus.

The Fibula (Calf Bone).

The **fibula** (Figs. 396, 397) is placed on the lateral side of the tibia, with which it is connected above and below. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones. Its upper extremity is small, placed toward the back of the head of the tibia, below the level of the knee-joint, and excluded from the formation of this joint. Its lower extremity inclines a little forward, so as to be on a plane anterior to that of the upper end; it projects below the tibia, and forms the lateral part of the ankle-joint. The bone has a **body** and **two extremities**.

The Upper Extremity or Head (*capitulum fibulae; proximal extremity*).—The upper extremity is of an irregular quadrate form, presenting above a flattened articular surface, directed upward, forward, and medialward, for articulation with a corresponding surface on the lateral condyle of the tibia. On the lateral side is a thick and rough prominence continued behind into a pointed eminence, the **apex** (*styloid process*), which projects upward from the posterior part of the head. The prominence, at its upper and lateral part, gives attachment to the tendon of the Biceps femoris and to the fibular collateral ligament of the knee-joint, the ligament dividing the tendon into two parts. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior fibres of the Peroneus longus, and a surface for the attachment of the anterior ligament of the head; and behind, another tubercle, for the attachment of the posterior ligament of the head and the origin of the upper fibres of the Soleus.

The Body or Shaft (*corpus fibulae*).—The body presents four borders—the antero-lateral, the antero-medial, the postero-lateral, and the postero-medial; and four surfaces—anterior, posterior, medial, and lateral.

Borders.—The **antero-lateral border** begins above in front of the head, runs vertically downward to a little below the middle of the bone, and then curving somewhat lateralward, bifurcates so as to embrace a triangular subcutaneous surface

immediately above the lateral malleolus. This border gives attachment to an intermuscular septum, which separates the Extensor muscles on the anterior surface of the leg from the Peronaei longus and brevis on the lateral surface.

The **antero-medial border**, or **interosseous crest**, is situated close to the medial side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it in the lower two-thirds. It begins above just beneath the head of the bone (sometimes it is quite indistinct for about 2.5 cm. below the head), and ends at the apex of a rough triangular surface immediately above the articular facet of the lateral malleolus. It serves for the attachment of the interosseous membrane, which separates the Extensor muscles in front from the Flexor muscles behind.

The **postero-lateral border** is prominent; it begins above at the apex, and ends below in the posterior border of the lateral malleolus. It is directed lateralward above, backward in the middle of its course, backward, and a little medialward below, and gives attachment to an aponeurosis which separates the Peronaei on the lateral surface from the Flexor muscles on the posterior surface.

The **postero-medial border**, sometimes called the **oblique line**, begins above at the medial side of the head, and ends by becoming continuous with the interosseous crest at the lower fourth of the bone. It is well-marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posterior from the Soleus and Flexor hallucis longus.

Surfaces.—The **anterior surface** is the interval between the antero-lateral and antero-medial borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the origin of three muscles: the Extensor digitorum longus, Extensor hallucis longus, and Peronaeus tertius.

The **posterior surface** is the space included between the postero-lateral and the postero-medial borders; it is continuous below with the triangular area above the articular surface of the lateral malleolus; it is directed backward above, backward and medialward at its middle, directly medialward below. Its upper third is rough, for the origin of the Soleus; its lower part presents a triangular surface, connected to the tibia by a strong interosseous ligament; the intervening part of the surface is covered by the fibres of origin of the Flexor hallucis longus. Near the middle of this surface is the nutrient foramen, which is directed downward.

The **medial surface** is the interval included between the antero-medial and the postero-medial borders. It is grooved for the origin of the Tibialis posterior.

The **lateral surface** is the space between the antero-lateral and postero-lateral borders. It is broad, and often deeply grooved; it is directed lateralward in the upper two-thirds of its course, backward in the lower third, where it is continuous with the posterior border of the lateral malleolus. This surface gives origin to the Peronaei longus and brevis.

The Lower Extremity or Lateral Malleolus (*malleolus lateralis; distal extremity; external malleolus*).—The lower extremity is of a pyramidal form, and somewhat flattened from side to side; it descends to a lower level than the medial malleolus. The **lateral surface** is convex, subcutaneous, and continuous with the triangular, subcutaneous surface on the lateral side of the body. The **medial surface** (Fig. 400) presents in front a smooth triangular surface, convex from above downward, which articulates with a corresponding surface on the lateral side of the talus. Behind and beneath the articular surface is a rough depression, which gives attachment to the posterior talofibular ligament. The **anterior border** is thick and rough, and marked below by a depression for the attachment of the anterior talofibular ligament. The **posterior border** is broad and presents the shallow **malleolar sulcus**, for the passage of the tendons of the Peronaei longus and brevis. The **summit** is rounded, and give attachment to the calcaneofibular ligament.

Articulations.—The fibula articulates with two bones: the tibia and talus.

Ossification.—The fibula is ossified from *three* centres (Fig. 401): one for the body, and one for either end. Ossification begins in the body about the eighth week of fetal life, and extends toward the extremities. At birth the ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper about the fourth year. The lower epiphysis, the first to ossify, unites with the body about the twentieth year; the upper epiphysis joins about the twenty-fifth year.

Applied Anatomy of the Tibia and Fibula. In fractures of the bones of the leg, both bones are generally involved, but either bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused by either direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle and lower thirds of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at a rather higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are for the most part the result of indirect violence, and the direction of the fracture is downward, forward, and medialward in many cases, but may be downward and lateralward, or downward and backward. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture of the tibia generally starts as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body while the foot is fixed.

For

FIG. 400.—Lower extremity of right fibula. Medial aspect.

FIG. 401.—Plan of ossification of the fibula. From three centres.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia is the bone which is most commonly and most extensively distorted in rickets. It bends at the junction of the middle and lower third, its weakest part, and presents a curve forward with generally some lateral displacement.

The tibia is more often the seat of acute infective necrosis than any other bone in the body, and with the formation of the sequestrum, a large amount of new bony material is thrown out by the periosteum. The sequence of events in this disease can be very closely followed in the case of the tibia, and it is not uncommon to find a patient from whom the whole diaphysis of the tibia has been removed, going about with a new bone entirely of periosteal formation. Chronic bone abscess is more frequently met with in the cancellous tissue of the head or lower end of the tibia than in any other bone in the body. These abscesses are very chronic, and in most cases the result of tuberculous osteitis, although they are sometimes due to the organisms of suppuration or even the *Bacillus typhosus*.

THE FOOT.

The skeleton of the foot (Figs. 403 and 404) consists of three parts: the **tarsus**, **metatarsus**, and **phalanges**.

The Tarsus (*Ossa Tarsi*).

The **tarsal bones** are seven in number, viz., the **calcaneus**, **talus**, **cuboid**, **navicular**, and the **first**, **second**, and **third cuneiforms**.

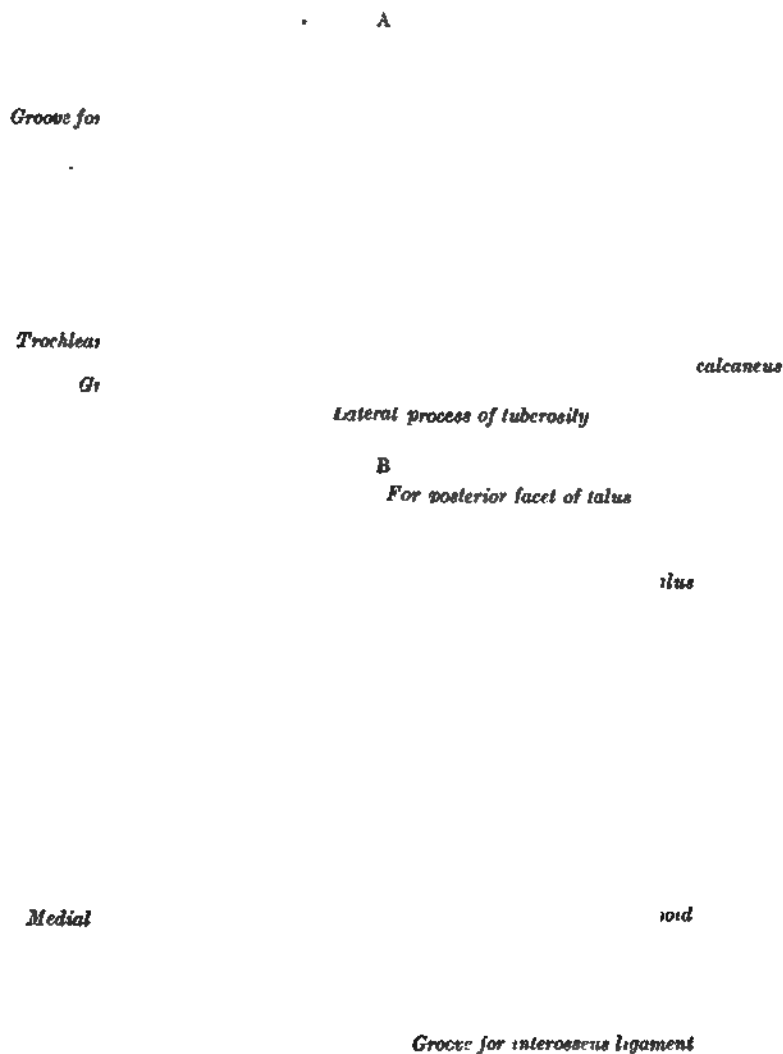

FIG. 402. The left calcaneus. A Postero-lateral view. B Antero-medial view.

The Calcaneus (*os calcis*) (Fig. 402).—The calcaneus is the largest of the tarsal bones. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It is irregularly cuboidal in form, having its long axis directed forward and lateralward; it presents for examination six surfaces.

Surfaces.—The **superior surface** extends behind on to that part of the bone which projects backward to form the heel. This varies in length in different individuals,

tendon of

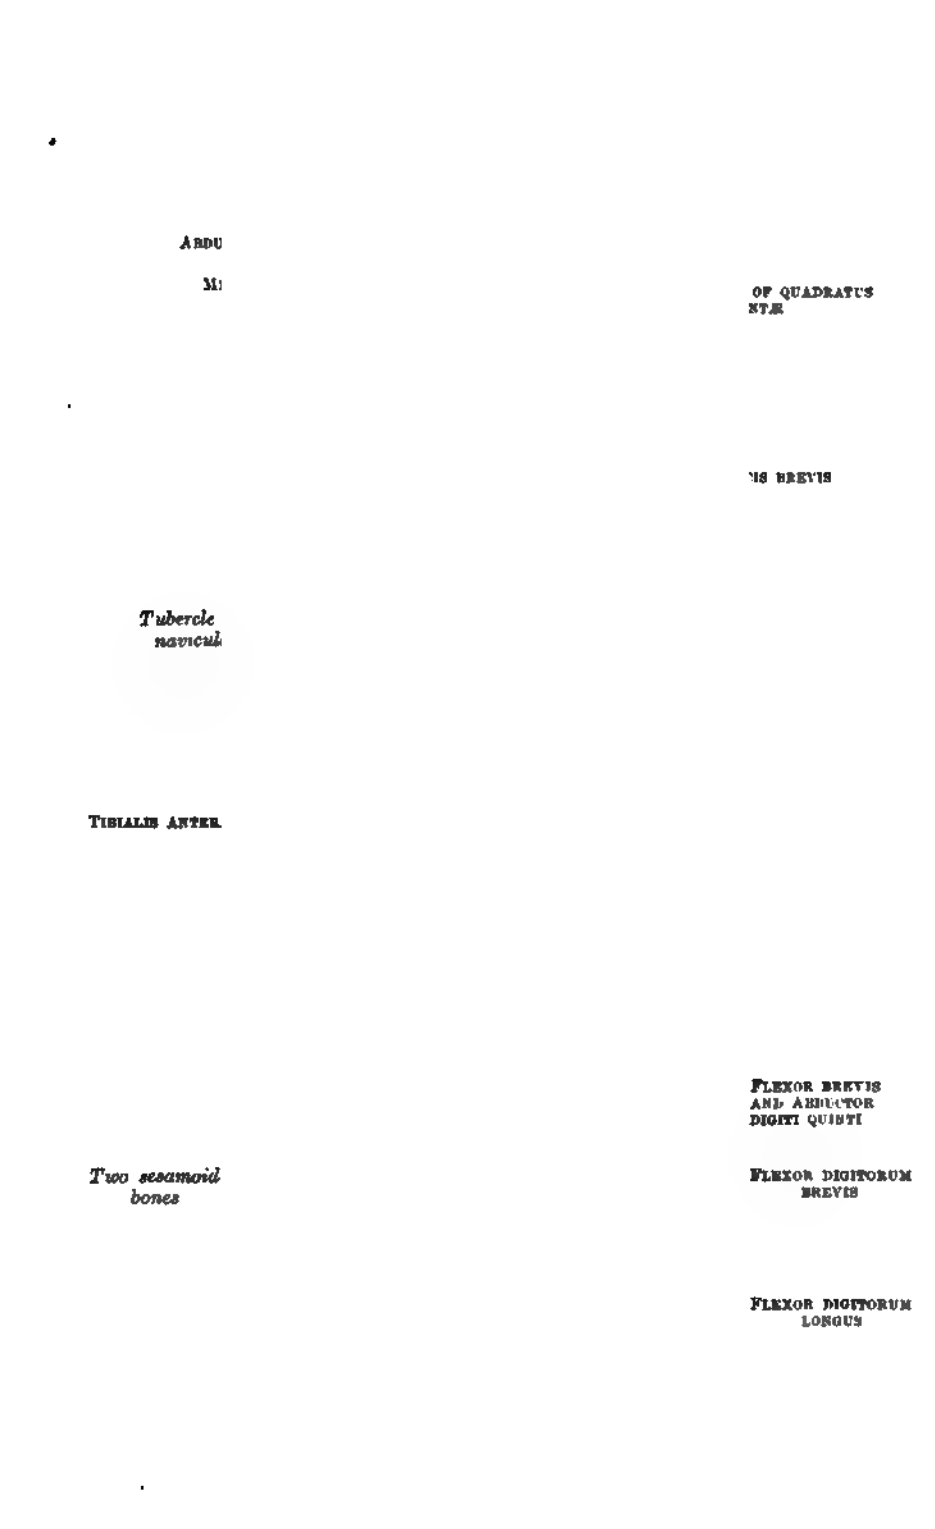

FIG. 404. -Bones of the right foot. Plantar surface

is convex from side to side, concave from before backward, and supports a mass of fat placed in front of the tendo calcaneus. In front of this area is a large usually somewhat oval-shaped facet, the **posterior articular surface**, which looks upward and forward; it is convex from behind forward, and articulates with the posterior calcaneal facet on the under surface of the talus. It is bounded anteriorly by a deep depression which is continued backward and medialward in the form of a groove, the **calcaneal sulcus**. In the articulated foot this sulcus lies below a similar one on the under surface of the talus, and the two form a canal (**sinus tarsi**) for the lodgement of the interosseous talocalcaneal ligament. In front and to the medial side of this groove is an elongated facet, concave from behind forward, and with its long axis directed forward and lateralward. This facet is frequently divided into two by a notch: of the two, the posterior, and larger is termed the **middle articular surface**; it is supported on a projecting process of bone, the **sustentaculum tali**, and articulates with the middle calcaneal facet on the under surface of the talus; the **anterior articular surface** is placed on the anterior part of the body, and articulates with the anterior calcaneal facet on the talus. The upper surface, anterior and lateral to the facets, is rough for the attachment of ligaments and for the origin of the Extensor digitorum brevis.

The **inferior or plantar surface** is uneven, wider behind than in front, and convex from side to side; it is bounded posteriorly by a transverse elevation, the **calcaneal tuberosity**, which is depressed in the middle and prolonged at either end into a process; the **lateral process**, small, prominent, and rounded, gives origin to part of the Abductor digiti quinti; the **medial process**, broader and larger, gives attachment, by its prominent medial margin, to the Abductor hallucis, and in front to the Flexor digitorum brevis and the plantar aponeurosis; the depression between the processes gives origin to the Abductor digiti quinti. The rough surface in front of the processes gives attachment to the long plantar ligament, and to the lateral head of the Quadratus plantae; while to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of the tubercle, is attached the plantar calcaneocuboid ligament.

The **lateral surface** is broad behind and narrow in front, flat and almost subcutaneous; near its centre is a tubercle, for the attachment of the calcaneofibular ligament. At its upper and anterior part, this surface gives attachment to the lateral talocalcaneal ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves. The grooves are separated by an elevated ridge, or tubercle, the **trochlear process (peroneal tubercle)**, which varies much in size in different bones. The **superior groove** transmits the tendon of the Peroneus brevis; the **inferior groove**, that of the Peroneus longus.

The **medial surface** is deeply concave; it is directed obliquely downward and forward, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords origin to part of the Quadratus plantae. At its upper and forepart is a horizontal eminence, the **sustentaculum tali**, which gives attachment to a slip of the tendon of the Tibialis posterior. This eminence is concave above, and articulates with the middle calcaneal articular surface of the talus; below, it is grooved for the tendon of the Flexor hallucis longus; its anterior margin gives attachment to the plantar calcaneonavicular ligament, and its medial, to a part of the deltoid ligament of the ankle-joint.

The **anterior or cuboid articular surface** is of a somewhat triangular form. It is concave from above downward and lateralward, and convex in a direction at right angles to this. Its medial border gives attachment to the plantar calcaneonavicular ligament.

The **posterior surface** is prominent, convex, wider below than above, and divisible into three areas. The lowest of these is rough, and covered by the fatty and fibrous tissue of the heel; the middle, also rough, gives insertion to the tendo calcaneus

and Plantaris; while the highest is smooth, and is covered by a bursa which intervenes between it and the tendo calcaneus.

Articulations.—The calcaneus articulates with two bones: the talus and cuboid.

FIG. 405.—The left talus. A Supero-lateral view B Infero-medial view C Inferior view

The Talus (*astragalus*; *ankle bone*) (Fig. 405).—The talus is the second largest of the tarsal bones. It occupies the middle and upper part of the tarsus, supporting the tibia above, resting upon the calcaneus below, articulating on either side with the malleoli, and in front with the navicular. It consists of a **body**, a **neck**, and a **head**.

The Body (*corpus tali*).—The **superior surface** of the body presents, behind, a smooth trochlear surface, the **trochlea**, for articulation with the tibia. The trochlea is broader in front than behind, convex from before backward, slightly concave from side to side: in front it is continuous with the upper surface of the neck of the bone.

The **inferior surface** presents two articular areas, the posterior and middle calcaneal surfaces, separated from one another by a deep groove, the **sulcus tali**. The groove runs obliquely forward and lateralward, becoming gradually broader and deeper in front: in the articulated foot it lies above a similar groove upon the upper surface of the calcaneus, and forms, with it, a canal (**sinus tarsi**) filled up in the recent state by the interosseous talocalcaneal ligament. The **posterior calcaneal articular surface** is large and of an oval or oblong form. It articulates with the corresponding facet on the upper surface of the calcaneus,¹ and is deeply concave in the direction of its long axis which runs forward and lateralward at an angle of about 45° with the median plane of the body. The **middle calcaneal articular surface** is small, oval in form and slightly convex; it articulates with the upper surface of the sustentaculum tali of the calcaneus.

The **medial surface** presents at its upper part a pear-shaped articular facet for the medial malleolus, continuous above with the trochlea; below the articular surface is a rough depression for the attachment of the deep portion of the deltoid ligament of the ankle-joint.

The **lateral surface** carries a large triangular facet, concave from above downward, for articulation with the lateral malleolus; its anterior half is continuous above with the trochlea; and in front of it is a rough depression for the attachment of the anterior talofibular ligament. Between the posterior half of the lateral border of the trochlea and the posterior part of the base of the fibular articular surface is a triangular facet (Fawcett²) which comes into contact with the transverse inferior tibiofibular ligament during flexion of the ankle-joint; below the base of this facet is a groove which affords attachment to the posterior talofibular ligament.

The **posterior surface** is narrow, and traversed by a groove running obliquely downward and medialward, and transmitting the tendon of the Flexor hallucis longus. Lateral to the groove is a prominent tubercle, the **posterior process**, to which the posterior talofibular ligament is attached; this process is sometimes separated from the rest of the talus, and is then known as the **os trigonum**. Medial to the groove is a second smaller tubercle.

The Neck (*collum tali*).—The neck is directed forward and medialward, and comprises the constricted portion of the bone between the body and the oval head. Its **upper and medial surfaces** are rough, for the attachment of ligaments; its **lateral surface** is concave and is continuous below with the deep groove for the interosseous talocalcaneal ligament.

The Head (*caput tali*).—The head looks forward and medialward; its **anterior articular or navicular surface** is large, oval, and convex. Its **inferior surface** has two facets, which are best seen in the recent condition. The medial, situated in front of the middle calcaneal facet, is convex, triangular, or semi-oval in shape, and rests on the plantar calcaneonavicular ligament; the lateral, named the **anterior calcaneal articular surface**, is somewhat flattened, and articulates with the facet on the upper surface of the anterior part of the calcaneus.

Articulations.—The talus articulates with *four* bones: tibia, fibula, calcaneus, and navicular.

The Cuboid Bone (*os cuboideum*) (Fig. 406).—The cuboid bone is placed on the lateral side of the foot, in front of the calcaneus, and behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed medialward.

¹ Sewell (Journal of Anatomy and Physiology, vol. xxxviii) pointed out that in about 10 per cent. of bones a small triangular facet, continuous with the posterior calcaneal facet, is present at the junction of the lateral surface of the body with the posterior wall of the sulcus tali.

² Edinburgh Medical Journal, 1895.

Surfaces.—The **dorsal surface**, directed upward and lateralward, is rough, for the attachment of ligaments. The **plantar surface** presents in front a deep groove, the **peroneal sulcus**, which runs obliquely forward and medialward; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which the long plantar ligament is attached. The ridge ends laterally in an eminence, the **tuberosity**, the surface of which presents an oval facet; on this facet glides the sesamoid bone or cartilage frequently found in the tendon of the Peroneus longus. The surface of bone behind the groove is rough, for the attachment of the plantar calcaneocuboid ligament, a few fibres of the Flexor hallucis brevis, and a fasciculus from the tendon of the Tibialis posterior. The **lateral surface** presents a deep notch formed by the commencement of the peroneal sulcus. The

FIG. 406.—The left cuboid. A Antero-medial view. B Postero-lateral view.

posterior surface is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the calcaneus; its infero-medial angle projects backward as a process which underlies and supports the anterior end of the calcaneus. The **anterior surface**, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets: the medial, quadrilateral in form, articulates with the fourth metatarsal; the lateral, larger and more triangular, articulates with the fifth. The **medial surface** is broad, irregularly quadrilateral, and presents at its middle and upper part a smooth oval facet, for articulation with the third cuneiform; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

Articulations.—The cuboid articulates with *four* bones: the calcaneus, third cuneiform, and fourth and fifth metatarsals; occasionally with a fifth, the navicular.

FIG. 407.—The left navicular. A Antero-lateral view B. Postero-medial view.

The Navicular Bone (*os naviculare pedis*; *scaphoid bone*) (Fig. 407).—The navicular bone is situated at the medial side of the tarsus, between the talus behind and the cuneiform bones in front.

Surfaces.—The **anterior surface** is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The **posterior surface** is oval, concave, broader laterally than medially, and articulates with the rounded head of the talus. The **dorsal surface** is convex from side to side, and rough for the attachment of ligaments. The **plantar surface** is irregular, and also rough for the attachment of ligaments. The **medial surface** presents a rounded **tuberosity**, the lower part of which gives attachment to part of the tendon of the Tibialis posterior. The **lateral surface** is rough and irregular for the attachment of ligaments, and occasionally presents a small facet for articulation with the cuboid bone.

Articulations.—The navicular articulates with *four* bones: the talus and the three cuneiforms; occasionally with a fifth, the cuboid.

The First Cuneiform Bone (*os cuneiform, primum; internal cuneiform*) (Fig. 408).—The first cuneiform bone is the largest of the three cuneiforms. It is situated at the medial side of the foot, between the navicular behind and the base of the first metatarsal in front.

Surfaces.—The **medial surface** is subcutaneous, broad, and quadrilateral; at its anterior plantar angle is a smooth oval impression, into which part of the tendon of the Tibialis anterior is inserted; in the rest of its extent it is rough for the attachment of ligaments. The **lateral surface** is concave, presenting, along its superior and posterior borders a narrow L-shaped surface, the vertical limb and posterior part of the horizontal limb

B. Postero-lateral view.

of which articulate with the second cuneiform, while the anterior part of the horizontal limb articulates with the second metatarsal bone; the rest of this surface is rough for the attachment of ligaments and part of the tendon of the Peroneus longus. The **anterior surface**, kidney-shaped and much larger than the posterior, articulates with the first metatarsal bone. The **posterior surface** is triangular, concave, and articulates with the most medial and largest of the three facets on the anterior surface of the navicular. The **plantar surface** is rough, and forms the base of the wedge; at its back part is a tuberosity for the insertion of part of the tendon of the Tibialis posterior. It also gives insertion in front to part of the tendon of the Tibialis anterior. The **dorsal surface** is the narrow end of the wedge, and is directed upward and lateralward; it is rough for the attachment of ligaments.

Articulations.—The first cuneiform articulates with *four* bones: the navicular, second cuneiform, and first and second metatarsals.

The Second Cuneiform Bone (*os cuneiforme secundum; middle cuneiform*) (Fig. 409).—The second cuneiform bone, the smallest of the three, is of very regular wedge-like form, the thin end being directed downward. It is situated between the other two cuneiforms, and articulates with the navicular behind, and the second metatarsal in front.

Surfaces.—The **anterior surface**, triangular in form, and narrower than the posterior, articulates with the base of the second metatarsal bone. The **posterior surface**, also triangular, articulates with the intermediate facet on the anterior surface

of the navicular. The **medial surface** carries an L-shaped articular facet, running along the superior and posterior borders, for articulation with the first cuneiform, and is rough in the rest of its extent for the attachment of ligaments. The **lateral**

surface presents posteriorly a smooth facet for articulation with the third cuneiform bone. The **dorsal surface** forms the base of the wedge; it is quadrilateral and rough for the attachment of ligaments. The **plantar surface**, sharp and tuberculated, is also rough for the attachment of ligaments, and for the insertion of a slip from the tendon of the Tibialis posterior.

Articulations.—The second cuneiform articulates with four bones: the navicular, first and third cuneiforms, and second metatarsal.

The Third Cuneiform Bone (*os cuneiforme tertium; external cuneiform*) (Fig. 410).—The third cuneiform bone, intermediate in size between the two preceding, is wedge-shaped, the base being uppermost. It occupies the centre of the front row of the tarsal bones, between the second cuneiform medially, the cuboid laterally, the navicular behind, and the third metatarsal in front.

Surfaces.—The **anterior surface**, triangular in form, articulates with the third metatarsal bone. The **posterior surface** articulates with the lateral facet on the anterior surface of the navicular, and is rough below for the attachment of ligamentous fibres. The **medial surface** presents an anterior and a posterior articular facet, separated by a rough depression: the anterior, sometimes divided, articulates with the lateral side of the base of the second metatarsal bone; the posterior skirts

the posterior border, and articulates with the second cuneiform; the rough depression gives attachment to an interosseous ligament. The **lateral surface** also presents two articular facets, separated by a rough non-articular area; the anterior facet, situated at the superior angle of the bone, is small and semi-oval in shape, and articulates with the medial side of the base of the fourth metatarsal bone; the posterior and larger one is triangular or oval, and articulates with the cuboid; the rough, non-articular area serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another; those for articulation with the second cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The **dorsal surface** is of an oblong form, its postero-lateral angle being prolonged backward. The **plantar surface** is a rounded margin, and serves for the attachment

of part of the tendon of the Tibialis posterior, part of the Flexor hallucis brevis, and ligaments.

Articulations.—The third cuneiform articulates with six bones: the navicular, second cuneiform, cuboid, and second, third, and fourth metatarsals.

The Metatarsus.

The metatarsus consists of five bones which are numbered from the medial side (*ossa metatarsalia* I.-V.); each presents for examination a body and two extremities.

Common Characteristics of the Metatarsal Bones.—The body is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is curved longitudinally, so as to be concave below, slightly convex above. The base or posterior extremity is wedge-shaped, articulating proximally with the tarsal bones, and by its sides with the contiguous metatarsal bones: its dorsal and plantar surfaces are rough for the attachment of ligaments. The head or anterior extremity presents a convex articular surface, oblong from above downward, and extending farther backward below than above. Its sides are flattened, and on each is a depression, surmounted by a tubercle, for ligamentous attachment. Its plantar surface is grooved antero-posteriorly for the passage of the Flexor tendons, and marked on either side by an articular eminence continuous with the terminal articular surface.

FIG. 412.—The second metatarsal. (Left.)

Characteristics of the Individual Metatarsal Bones.—The **First Metatarsal Bone** (*os metatarsale I*; *metatarsal bone of the great toe*) (Fig. 411).—The first metatarsal bone is remarkable for its great thickness, and is the shortest of the metatarsal bones. The **body** is strong, and of well-marked prismoid form. The **base** presents, as a rule, no articular facets on its sides, but occasionally on the lateral side there is an oval facet, by which it articulates with the second metatarsal. Its proximal articular surface is of large size and kidney-shaped; its

circumference is grooved, for the tarsometatarsal ligaments, and medially gives insertion to part of the tendon of the *Tibialis anterior*; its plantar angle presents a rough oval prominence for the insertion of the tendon of the *Peroneus longus*. The **head** is large; on its plantar surface are two grooved facets, on which glide sesamoid bones; the facets are separated by a smooth elevation.

The Second Metatarsal Bone (*os metatarsale II*) (Fig. 412).—The second metatarsal bone is the longest of the metatarsal bones, being prolonged backward into the recess formed by the three cuneiform bones. Its **base** is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the second cuneiform; one at the upper part of its medial surface, for articulation with the first cuneiform; and two on its lateral surface, an upper and lower, separated by a rough non-articular interval. Each of these lateral articular surfaces is divided into two by a vertical ridge; the two anterior facets articulate with the third metatarsal; the two posterior (sometimes continuous) with the third cuneiform. A fifth facet is occasionally present for articulation with the first metatarsal; it is oval in shape, and is situated on the medial side of the body near the base.

FIG. 413.—The third metatarsal. (Left)

FIG. 414.—The fourth metatarsal. (Left)

The Third Metatarsal Bone (*os metatarsale III*) (Fig. 413).—The third metatarsal bone articulates proximally, by means of a triangular smooth surface, with the third cuneiform; medially, by two facets, with the second metatarsal; and laterally, by a single facet, with the fourth metatarsal. This last facet is situated at the dorsal angle of the base.

The Fourth Metatarsal Bone (*os metatarsale IV*) (Fig. 414).—The fourth metatarsal bone is smaller in size than the preceding; its **base** presents an oblique quadrilateral surface for articulation with the cuboid; a smooth facet on the medial side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior portion for articulation with the third cuneiform; on the lateral side a single facet, for articulation with the fifth metatarsal.

The Fifth Metatarsal Bone (*os metatarsale V*) (Fig. 415).—The fifth metatarsal bone is recognized by a rough eminence, the **tuberosity**, on the lateral side of its

base. The **base** articulates behind, by a triangular surface cut obliquely in a transverse direction, with the cuboid; and medially, with the fourth metatarsal. On the medial part of its dorsal surface is inserted the tendon of the *Peronaeus tertius* and on the dorsal surface of the tuberosity that of the *Peronaeus brevis*. A strong band of the plantar aponeurosis connects the projecting part of the tuberosity with the lateral process of the tuberosity of the calcaneus. The plantar surface of the base is grooved for the tendon of the *Abductor digiti quinti*, and gives origin to the *Flexor digiti quinti brevis*.

For
metatarsal For cuboid Tuberosity

FIG. 415.—The fifth metatarsal (Left.)

Articulations.—The base of each metatarsal bone articulates with one or more of the tarsal bones, and the head with one of the first row of phalanges. The first metatarsal articulates with the first cuneiform, the second with all three cuneiforms, the third with the third cuneiform, the fourth with the third cuneiform and the cuboid, and the fifth with the cuboid.

The Phalanges of the Foot (*Phalanges Digitorum Pedis*).

The **phalanges** of the foot correspond, in number and general arrangement, with those of the hand; there are two in the great toe, and three in each of the other toes. They differ from them, however, in their size, the bodies being much reduced in length, and, especially in the first row, laterally compressed.

First Row.—The phalanges of the first row closely resemble those of the hand. The **body** of each is compressed from side to side, convex above, concave below. The **base** is concave; and the **head** presents a trochlear surface for articulation with the second phalanx.

Second Row.—The phalanges of the second row are remarkably small and short, but rather broader than those of the first row.

The **ungual phalanges**, in form, resemble those of the fingers; but they are smaller and are flattened from above downward; each presents a broad base for articulation with the corresponding bone of the second row, and an expanded distal extremity for the support of the nail and end of the toe.

Articulations.—In the second, third, fourth, and fifth toes the phalanges of the first row articulate behind with the metatarsal bones, and in front with the second phalanges, which in their turn articulate with the first and third: the unguinal phalanges articulate with the second. In

the great toe the first phalanx articulates proximally with the metatarsal bone and distally with the ungual phalanx.

Ossification of the Bones of the Foot (Fig. 416).—The tarsal bones are each ossified from a single centre, excepting the calcaneus, which has an epiphysis for its posterior extremity.¹ The centres make their appearance in the following order: calcaneus at the sixth month of fetal life; talus, about the seventh month; cuboid, at the ninth month; third cuneiform, during the first year; first cuneiform, in the third year; second cuneiform and navicular, in the fourth year. The epiphysis for the posterior extremity of the calcaneus appears at the tenth year, and unites with the rest of the bone soon after puberty. The posterior process of the talus is sometimes ossified from a separate centre, and may remain distinct from the main mass of the bone, when it is named the *os trigonum*.

FIG. 416.—Plan of ossification of the foot.

The metatarsal bones are each ossified from two centres: one for the body, and one for the head, of the second, third, fourth, and fifth metatarsals; one for the body, and one for the base, of the first metatarsal.¹ Ossification commences in the centre of the body about the ninth week, and extends toward either extremity. The centre for the base of the first metatarsal appears about the third year; the centres for the heads of the other bones between the fifth and eighth years; they join the bodies between the eighteenth and twentieth years.

The phalanges are each ossified from two centres: one for the body, and one for the base. The centre for the body appears about the tenth week, that for the base between the fourth and tenth years; it joins the body about the eighteenth year.

¹ As was noted in the first metacarpal (see footnote, page 332), so in the first metatarsal, there is often a second epiphysis for its head.

Comparison of the Bones of the Hand and Foot.

The hand and foot are constructed on somewhat similar principles, each consisting of a proximal part, the carpus or the tarsus, a middle portion, the metacarpus, or the metatarsus, and a terminal portion, the phalanges. The proximal part consists of a series of more or less cubical bones which allow a slight amount of gliding on one another and are chiefly concerned in distributing forces transmitted to or from the bones of the arm or leg. The middle part is made up of slightly movable long bones which assist the carpus or tarsus in distributing forces and also give greater breadth for the reception of such forces. The separation of the individual bones from one another allows of the attachments of the Interossei and protects the dorsi-palmar and dorsi-plantar vascular anastomoses. The terminal portion is the most movable, and its separate elements enjoy a varied range of movements, the chief of which are flexion and extension.

The function of the hand and foot are, however, very different, and the general similarity between them is greatly modified to meet these requirements. Thus the foot forms a firm basis of support for the body in the erect posture, and is therefore more solidly built up and its component parts are less movable on each other than those of the hand. In the case of the phalanges the difference is readily noticeable; those of the foot are smaller and their movements are more limited than those of the hand. Very much more marked is the difference between the metacarpal bone of the thumb and the metatarsal bone of the great toe. The metacarpal bone of the thumb is constructed to permit of great mobility, is directed at an acute angle from that of the index finger, and is capable of a considerable range of movements at its articulation with the carpus. The metatarsal bone of the great toe assists in supporting the weight of the body, is constructed with great solidity, lies parallel with the other metatarsals, and has a very limited degree of mobility. The carpus is small in proportion to the rest of the hand, is placed in line with the forearm, and forms a transverse arch, the concavity of which constitutes a bed for the Flexor tendons and the palmar vessels and nerves. The tarsus forms a considerable part of the foot, and is placed at right angles to the leg, a position which is almost peculiar to man, and has relation to his erect posture. In order to allow of their supporting the weight of the body with the least expenditure of material the tarsus and a part of the metatarsus are constructed in a series of arches (Figs. 417, 418), the disposition of which will be considered after the articulations of the foot have been described.

Applied Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface, and joined together by very strong ligaments which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence; and, as there is only a very scanty amount of soft parts over the bones, the fractures are very often compound, and amputation is often necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group—that is, of the calcaneus and talus—are usually produced by falls from a height on to the feet.

In club-foot (*talipes*), especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is principally the case in congenital *talipes equinovarus*, in which the head of the talus becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the navicular. The tarsal bones are peculiarly liable to become the seat of tuberculous caries following comparatively trivial injuries, especially as they are not maintained in a condition of rest to the same extent as some other parts of the body after similar injuries. Caries of the calcaneus or talus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder

frequently become involved, since the disease spreads through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the foot is often required either for injury or disease. The principal amputations are as follows: (1) Syme's: amputation at the ankle-joint by a heel flap, with removal of

FIG. 417.—Skeleton of foot. Medial aspect.

the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Pirogoff's: amputation of the whole of the tarsal bones (except the posterior part of the calcaneus), and a thin slice from the tibia and fibula, including the two malleoli. The sawn surface of the calcaneus is then turned up and united to the cut surface of the tibia. (3) Subastragalar: amputation of the foot below the talus through the joint between it and the calcaneus.

FIG. 418.—Skeleton of foot. Lateral aspect.

The bones of the tarsus occasionally require removal individually. This is especially the case with the talus for tuberculous disease limited to that bone; or the talus may require excision in cases of subastragalar dislocation, or in cases of inveterate talipes. The cuboid has been removed for the same reason.

Fractures of the metatarsal bones and phalanges are nearly always the result of direct violence, and in the majority of cases the injury is caused by severe crushing accidents, necessitating amputation. The metatarsal bones, and especially that of the great toe, are frequently diseased, either in tuberculous subjects or in patients with perforating ulcer of the foot.

The Sesamoid Bones (*Ossa Sesamoides*).

Sesamoid bones are small more or less rounded masses embedded in certain tendons and usually related to joint surfaces. Their functions probably are to modify pressure, to diminish friction, and occasionally to alter the direction of a muscle pull. That they are not developed to meet certain physical requirements in the adult is evidenced by the fact that they are present as cartilaginous nodules in the fetus, and in greater numbers than in the adult. They must be regarded, according to Thilenius, as integral parts of the skeleton phylogenetically inherited.¹

¹ *Morpholog. Arbeiten*, 1906, v, 309

Physical necessities probably come into play in selecting and in regulating the degree of development of the original cartilaginous nodules. Nevertheless, irregular nodules of bone may appear as the result of intermittent pressure in certain regions, *e. g.*, the "rider's bone," which is occasionally developed in the Adductor muscles of the thigh.

Sesamoid bones are invested by the fibrous tissue of the tendons, except on the surfaces in contact with the parts over which they glide, where they present smooth articular facets.

In the upper extremity the sesamoid bones of the joints are found only on the palmar surface of the hand. Two, of which the medial is the larger, are constant at the metacarpophalangeal joint of the thumb; one is frequently present in the corresponding joint of the little finger, and one (or two) in the same joint of the index finger. Sesamoid bones are also found occasionally at the metacarpophalangeal joints of the middle and ring fingers, at the interphalangeal joint of the thumb and at the distal interphalangeal joint of the index finger.

In the lower extremity the largest sesamoid bone of the joints is the patella, developed in the tendon of the Quadriceps femoris. On the plantar aspect of the foot, two, of which the medial is the larger, are always present at the metatarsophalangeal joint of the great toe; one sometimes at the metatarsophalangeal joints of the second and fifth toes, one occasionally at the corresponding joint of the third and fourth toes, and one at the interphalangeal joint of the great toe.

Sesamoid bones apart from joints are seldom found in the tendons of the upper limb; one is sometimes seen in the tendon of the Biceps brachii opposite the radial tuberosity. They are, however, present in several of the tendons of the lower limb, *viz.*, one in the tendon of the Peroneus longus, where it glides on the cuboid; one, appearing late in life, in the tendon of the Tibialis anterior, opposite the smooth facet of the first cuneiform bone; one in the tendon of the Tibialis posterior, opposite the medial side of the head of the talus; one in the lateral head of the Gastrocnemius, behind the lateral condyle of the femur; and one in the tendon of the Psoas major, where it glides over the pubis. Sesamoid bones are found occasionally in the tendon of the Gluteus maximus, as it passes over the greater trochanter, and in the tendons which wind around the medial and lateral malleoli.

SYNDESMOLOGY.

THE bones of the skeleton are joined to one another at different parts of their surfaces, and such connections are termed **Joints** or **Articulations**. Where the joints are *immovable*, as in the articulations between practically all the bones of the skull, the adjacent margins of the bones are almost in contact, being separated merely by a thin layer of fibrous membrane, named the **sutural ligament**. In certain regions at the base of the skull this fibrous membrane is replaced by a layer of cartilage. Where *slight movement* combined with great strength is required, the osseous surfaces are united by tough and elastic **fibrocartilages**, as in the joints between the vertebral bodies, and in the interpubic articulation. In the *freely movable* joints the surfaces are completely separated; the bones forming the articulation are expanded for greater convenience of mutual connection, covered by **cartilage** and enveloped by **capsules** of fibrous tissue. The cells lining the interior of the fibrous capsule form an imperfect membrane—the **synovial membrane**—which secretes a lubricating fluid. The joints are strengthened by strong fibrous bands called **ligaments**, which extend between the bones forming the joint.

Bone.—Bone constitutes the fundamental element of all the joints. In the long bones, the extremities are the parts which form the articulations; they are generally somewhat enlarged; and consist of spongy cancellous tissue with a thin coating of compact substance. In the flat bones, the articulations usually take place at the edges; and in the short bones at various parts of their surfaces. The layer of compact bone which forms the joint surface, and to which the articular cartilage is attached, is called the **articular lamella**. It differs from ordinary bone tissue in that it contains no Haversian canals, and its lacunæ are larger and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently denser and firmer than ordinary bone, and is evidently designed to form an unyielding support for the articular cartilage.

Articular Cartilage.—Articular cartilage, which covers the articular surfaces of bones, and **fibrocartilages**, which enters into the structure of some of the joints, are described in the section on Histology (pages 47 and 48).

Ligaments.—Ligaments are composed mainly of bundles of **white fibrous tissue** placed parallel with, or closely interlaced with one another, and present a white, shining, silvery appearance. They are pliant and flexible, so as to allow perfect freedom of movement, but strong, tough, and inextensible, so as not to yield readily to applied force. Some ligaments consist entirely of **yellow elastic tissue**, as the *ligamenta flava* which connect together the laminae of adjacent vertebrae, and the *ligamentum nuchae* in the lower animals. In these cases the elasticity of the ligament is intended to act as a substitute for muscular power.

The Articular Capsules.—The articular capsules form complete envelopes for the freely movable joints. Each capsule consists of two strata—an **external** (*stratum fibrosum*) composed of white fibrous tissue, and an **internal** (*stratum synoviale*) which is a secreting layer, and is usually described separately as the synovial membrane.

The **fibrous capsule** is attached to the whole circumference of the articular end of each bone entering into the joint, and thus entirely surrounds the articulation.

The **synovial membrane** invests the inner surface of the fibrous capsule, and is reflected over any tendons passing through the joint cavity, as the tendon of the Popliteus in the knee, and the tendon of the Biceps brachii in the shoulder. It is composed of a thin, delicate, connective tissue, with branched connective-tissue corpuscles. Its secretion is thick, viscid, and glairy, like the white of an egg, and is hence termed **synovia**. In the fetus this membrane is said, by Toynbee, to be continued over the surfaces of the cartilages; but in the adult such a continuation is wanting, excepting at the circumference of the cartilage, upon which it encroaches for a short distance and to which it is firmly attached. In some of the joints the synovial membrane is thrown into folds which pass across the cavity; they are especially distinct in the knee. In other joints there are flattened folds, subdivided at their margins into fringe-like processes which contain convoluted vessels. These folds generally project from the synovial membrane near the margin of the cartilage, and lie flat upon its surface. They consist of connective tissue, covered with endothelium, and contain fat cells in variable quantities, and, more rarely, isolated cartilage cells; the larger folds often contain considerable quantities of fat.

Closely associated with synovial membrane, and therefore conveniently described in this section, are the mucous sheaths of tendons and the mucous bursæ.

Mucous sheaths (*vaginae mucosae*) serve to facilitate the gliding of tendons in fibroöseous canals. Each sheath is arranged in the form of an elongated closed sac, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the enclosed tendon. These sheaths are chiefly found surrounding the tendons of the Flexor and Extensor muscles of the fingers and toes as they pass through fibroöseous canals in or near the hand and foot.

Bursae mucosae are interposed between surfaces which glide upon each other. They consist of closed sacs containing a minute quantity of clear viscid fluid, and may be grouped, according to their situations, under the headings *subcutaneous*, *submuscular*, *subfacial*, and *subtendinous*.

CLASSIFICATION OF JOINTS.

The articulations are divided into three classes: **synarthroses** or immovable, **amphiarthroses** or slightly movable, and **diarthroses** or freely movable, joints.

Synarthroses (*immovable articulations*).—Synarthroses include all those articulations in which the surfaces of the bones are in almost direct contact, fastened together by intervening connective tissue or hyaline cartilage, and in which there is no appreciable motion, as in the joints between the bones of the skull, excepting those of the mandible. There are four varieties of synarthrosis: **sutura**, **schindylesis**, **gomphosis**, and **synchondrosis**.

FIG. 419.—Section across the sagittal suture.

FIG. 420.—Section through occipitosphenoïd synchondrosis of an infant.

Sutura.—Sutura is that form of articulation where the contiguous margins of the bones are united by a thin layer of fibrous tissue; it is met with only in the skull (Fig. 419). When the margins of the bones are connected by a series of processes, and indentations interlocked together, the articulation is termed a **true suture**

(*sutura vera*); and of this there are three varieties: *sutura dentata*, *serrata*, and *limbosa*. The margins of the bones are not in direct contact, being separated by a thin layer of fibrous tissue, continuous externally with the pericranium, internally with the dura mater. The *sutura dentata* is so called from the tooth-like form of the projecting processes, as in the suture between the parietal bones. In the *sutura serrata* the edges of the bones are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the *sutura limbosa*, there is besides the interlocking, a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed a *false suture* (*sutura notha*), of which there are two kinds: the *sutura squamosa*, formed by the overlapping of contiguous bones by broad bevelled margins, as in the squamosal suture between the temporal and parietal, and the *sutura harmonia*, where there is simple apposition of contiguous rough surfaces, as in the articulation between the maxillæ, or between the horizontal parts of the palatine bones.

Schindylesis.—Schindylesis is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminae in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the maxillæ and between the palatine bones.

Gomphosis.—Gomphosis is articulation by the insertion of a conical process into a socket; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulations of the roots of the teeth with the alveoli of the mandible and maxillæ.

Synchondrosis. Where the connecting medium is cartilage the joint is termed a synchondrosis (Fig. 420). This is a temporary form of joint, for the cartilage is converted into bone before adult life. Such joints are found between the epiphyses and bodies of long bones, between the occipital and the sphenoid at, and for some years after, birth, and between the petrous portion of the temporal and the jugular process of the occipital.

Amphiarthroses (*slightly movable articulations*).—In these articulations the contiguous bony surfaces are either connected by broad flattened disks of fibrocartilage, of a more or less complex structure, as in the articulations between the bodies of the vertebræ; or are united by an interosseous ligament, as in the inferior tibiofibular articulation. The first form is termed a **symphysis** (Fig. 421), the second a **syndesmosis**.

Disc of
fibrocartil
Articular cart

Diarthroses (*freely movable articulations*).—This class includes the greater number of the joints in the body. In a diarthrodial joint the contiguous bony surfaces are covered with articular cartilage, and connected by ligaments lined by synovial membrane (Fig. 422). The joint may be divided, completely or incompletely, by an **articular disk** or **meniscus**, the periphery of which is continuous with the fibrous capsule while its free surfaces are covered by synovial membrane (Fig. 423).

FIG. 421.—Diagrammatic section of a symphysis.

The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial, that is to say, all movements take place around one axis. In one form, the **ginglymus**, this axis is, practically speaking, transverse; in the other, the **trochoid** or **pivot-joint**, it is longitudinal. There are two varieties where the movement is biaxial, or around two horizontal axes at right angles to each other, or at any intervening

axis between the two. These are the **condyloid** and the **saddle-joint**. There is one form where the movement is polyaxial, the **enarthrosis** or **ball-and-socket joint**; and finally there are the **arthrodia** or **gliding joints**.

FIG. 423.—Diagrammatic section of a diarthrodial joint, with an articular disk.

Ginglymus or Hinge-joint.—In this form the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forward and backward, the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is seldom in the same plane as that of the axis of the proximal bone; there is usually a certain amount of deviation from the straight line during flexion. The articular surfaces are connected together by strong collateral ligaments, which form their chief bond of union. The best examples of ginglymus are the interphalangeal joints and the joint between the humerus and ulna; the knee- and ankle-joints are less typical, as they allow a slight degree of rotation or of side-to-side movement in certain positions of the limb.

Trochoid or Pivot-joint (*articulatio trochoidea; rotary joint*).—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or a ring on a pivot, the ring being formed partly of bone, partly of ligament. In the proximal radioulnar articulation, the ring is formed by the radial notch of the ulna and the annular ligament; here, the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas the ring is formed in front by the anterior arch, and behind by the transverse ligament of the atlas; here, the ring rotates around the odontoid process.

Condyloid Articulation (*articulatio ellipsoidea*).—In this form of joint, an ovoid articular surface, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The wrist-joint is an example of this form of articulation.

Articulation by Reciprocal Reception (*articulatio sellaris; saddle-joint*).—In this variety the opposing surfaces are reciprocally concavo-convex. The movements are the same as in the preceding form; that is to say, flexion, extension, adduction, abduction, and circumduction are allowed; but no axial rotation. The best example of this form is the carpometacarpal joint of the thumb.

Enarthrosis (*ball-and-socket joints*).—Enarthrosis is a joint in which the distal bone is capable of motion around an indefinite number of axes, which have one common centre. It is formed by the reception of a globular head into a cup-like cavity, hence the name "ball-and-socket." Examples of this form of articulation are found in the hip and shoulder.

Arthrodia (*gliding joints*) is a joint which admits of only gliding movement; it is formed by the apposition of plane surfaces, or one slightly concave, the other slightly convex, the amount of motion between them being limited by the ligaments

or osseous processes surrounding the articulation. It is the form present in the joints between the articular processes of the vertebræ, the carpal joints, except that of the capitate with the navicular and lunate, and the tarsal joints with the exception of that between the talus and the navicular.

THE KINDS OF MOVEMENT ADMITTED IN JOINTS.

The movements admissible in joints may be divided into four kinds: **gliding** and **angular movements**, **circumduction**, and **rotation**. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that only one kind of motion is found in any particular joint.

Gliding Movement.—Gliding movement is the simplest kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints; but in some, as in most of the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form.

Angular Movement.—Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place: (1) forward and backward, constituting flexion and extension; or (2) toward and from the median plane of the body, or, in the case of the fingers or toes, from the middle line of the hand or foot, constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip, the shoulder, the wrist, and the carpometacarpal joint of the thumb.

Circumduction.—Circumduction is that form of motion which takes place between the head of a bone and its articular cavity, when the bone is made to circumscribe a conical space; the base of the cone is described by the distal end of the bone, the apex is in the articular cavity; this kind of motion is best seen in the shoulder and hip-joints.

Rotation.—Rotation is a form of movement in which a bone moves around a central axis without undergoing any displacement from this axis; the axis of rotation may lie in a separate bone, as in the case of the pivot formed by the odontoid process of the axis vertebræ around which the atlas turns; or a bone may rotate around its own longitudinal axis, as in the rotation of the humerus at the shoulder-joint; or the axis of rotation may not be quite parallel to the long axis of the bone, as in the movement of the radius on the ulna during pronation and supination of the hand, where it is represented by a line connecting the centre of the head of the radius above with the centre of the head of the ulna below.

Ligamentous Action of Muscles.—The movements of the different joints of a limb are combined by means of the long muscles passing over more than one joint. These, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other—the latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed so as to bring their attachments nearer together. The uses of this arrangement are threefold: (1) It coördinates the kinds of movements which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. (2) It enables the short muscles which pass over only one joint to act upon more than one. (3) It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary.

Applied Anatomy.—W. W. Keen points out how important it is “that the surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist

after Colles' fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed as in 'making a fist,' flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed."

The articulations may be grouped into those of the trunk, and those of the upper and lower extremities.

ARTICULATIONS OF THE TRUNK.

These may be divided into the following groups, viz.:

- | | |
|--|--|
| I. Of the Vertebral Column. | VI. Of the Cartilages of the Ribs with the Sternum, and with Each Other. |
| II. Of the Atlas with the Axis. | VII. Of the Sternum. |
| III. Of the Vertebral Column with the Cranium. | VIII. Of the vertebral Column with the Pelvis. |
| IV. Of the Mandible. | IX. Of the Pelvis. |
| V. Of the Ribs with the Vertebrae. | |

I. Articulations of the Vertebral Column.

The articulations of the vertebral column consist of (1) a series of amphiarthrodial joints between the vertebral bodies, and (2) a series of diarthrodial joints between the vertebral arches.

1. **Articulations of Vertebral Bodies** (*intercentral ligaments*).—The articulations between the bodies of the vertebrae are amphiarthrodial joints, and the individual vertebrae move only slightly on each other. When, however, this slight degree of movement between the pairs of bones takes place in all the joints of the vertebral column, the total range of movement is very considerable. The ligaments of these articulations are the following:

The Anterior Longitudinal. The Posterior Longitudinal.
The Intervertebral Fibrocartilages.

The Anterior Longitudinal Ligament (*ligamentum longitudinale anterius; anterior common ligament*) (Figs. 424, 435).—The anterior longitudinal ligament is a broad and strong band of fibres, which extends along the anterior surfaces of the bodies of the vertebrae, from the axis to the sacrum. It is broader below than above, thicker in the thoracic than in the cervical and lumbar regions, and somewhat thicker opposite the bodies of the vertebrae than opposite the intervertebral fibrocartilages. It is attached, above, to the body of the axis, where it is continuous with the anterior atlantoaxial ligament, and extends down as far as the upper part of the front of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral fibrocartilages and the prominent margins of the vertebrae, but not to the middle parts of the bodies. In the latter situation the ligament is thick and serves to fill up the concavities on the anterior surfaces, and to make the front of the vertebral column more even. It is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial fibres are the longest and extend between four or five vertebrae. A second, subjacent set extends between two or three vertebrae; while a third set, the shortest and deepest, reaches from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres which pass from one vertebra to the next, separated from the concavities of the vertebral bodies by oval apertures for the passage of vessels.

The Posterior Longitudinal Ligament (*ligamentum longitudinale posterius; posterior common ligament*) (Figs. 424, 425).—The posterior longitudinal ligament is situated within the vertebral canal, and extends along the posterior surfaces of the bodies

FIG. 424.—Median sagittal section of two lumbar vertebrae and their ligaments.

of the vertebrae, from the body of the axis, where it is continuous with the *membrana tectoria*, to the sacrum. It is broader above than below, and thicker in the thoracic than in the cervical and lumbar regions. In the situation of the intervertebral fibrocartilages and contiguous margins of the vertebrae, where the ligament is more intimately adherent, it is broad, and in the thoracic and lumbar regions presents a series of dentations with intervening concave margins; but it is narrow and thick over the centres of the bodies, from which it is separated by the basivertebral veins. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and consists of superficial layers occupying the interval between three or four vertebrae, and deeper layers which extend between adjacent vertebrae.

The Intervertebral Fibrocartilages (*fibrocartilagineae intervertebrales; intervertebral disks*) (Figs. 424, 436).—The intervertebral fibrocartilages are interposed between the adjacent surfaces of the bodies of the vertebrae, from the axis to the sacrum, and form the chief bonds of connection between the vertebrae. They vary in shape, size, and thickness, in different parts of the verte-

bral column. In *shape* and *size* they correspond with the surfaces of the bodies between which they are placed, except in the cervical region, where they are slightly smaller from side to side than the corresponding bodies. In *thickness* they vary

FIG. 425.—Posterior longitudinal ligament, in the thoracic region.

not only in the different regions of the column, but in different parts of the same fibrocartilage; they are thicker in front than behind in the cervical and lumbar regions, and thus contribute to the anterior convexities of these parts of the column; while they are of nearly uniform thickness in the thoracic region, the anterior concavity of this part of the column being almost entirely owing to the shape of the vertebral bodies. The intervertebral fibrocartilages constitute about one-fourth of the length of the vertebral column, exclusive of the first two vertebræ; but this amount is not equally distributed between the various bones, the cervical and lumbar portions having, in proportion to their length, a much greater amount than the thoracic region, with the result that these parts possess greater pliancy and freedom of movement. The intervertebral fibrocartilages are adherent, by their surfaces, to thin layers of hyaline cartilage which cover the upper and under surfaces of the bodies of the vertebræ; in the lower cervical vertebræ, however, small joints lined by synovial membrane are occasionally present between the upper surfaces of the bodies and the margins of the fibrocartilages on either side. By their circumferences the intervertebral fibrocartilages are closely connected in front to the anterior, and behind to the posterior, longitudinal ligaments. In the thoracic region they are joined laterally, by means of the inter-articular ligaments, to the heads of those ribs which articulate with two vertebræ.

Structure of the Intervertebral Fibrocartilages.—Each is composed, at its circumference, of laminae of fibrous tissue and fibrocartilage, forming the *annulus fibrosus*; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish color, which projects considerably above the surrounding level when the disk is divided horizontally. This pulpy substance (*nucleus pulposus*), especially well-developed in the lumbar region, is the remains of the notochord. The laminae are arranged concentrically; the outermost consist of ordinary fibrous tissue, the others of white fibrocartilage. The laminae are not quite vertical in their direction, those near the circumference being curved outward and closely approximated; while those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each lamina is composed are directed, for the most part, obliquely from above downward, the fibres of adjacent laminae passing in opposite directions and varying in every layer; so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each fibrocartilage. The pulpy substance presents no such arrangement, and consists of a fine fibrous matrix, containing angular cells united to form a reticular structure.

Applied Anatomy.—When an aneurism presses on the vertebral column, the vertebral bodies are often deeply eroded by the tumor, while the intervertebral fibrocartilages remain intact. The fibrocartilages are the first to be destroyed, however, in tuberculosis of the vertebral column, where, as not infrequently happens, the disease begins in the fibrocartilages, and spreads thence to the bodies of the two adjoining vertebræ simultaneously.

2. Articulations of Vertebral Arches.—The joints between the articular processes of the vertebræ belong to the arthrodial variety and are enveloped by capsules lined by synovial membranes; while the laminae spinous and transverse processes are connected by the following ligaments:

The Ligamenta Flava.
The Supraspinal.

The Ligamentum Nuchae.
The Interspinal.

The Intertransverse.

The Articular Capsules (*capsulae articulares*; *capsular ligaments*) (Fig. 424).—The articular capsules are thin and loose, and are attached to the margins of the articular processes of adjacent vertebræ. They are longer and looser in the cervical than in the thoracic and lumbar regions.

The Ligamenta Flava (*ligamenta subflava*) (Fig. 426).—The ligamenta flava connect the laminae of adjacent vertebræ, from the axis to the first segment of the sacrum. They are best seen from the interior of the vertebral canal; when looked at from the outer surface they appear short, being overlapped by the laminae. Each ligament

consists of two lateral portions which commence one on either side of the roots of the articular processes, and extend backward to the point where the laminae meet to form the spinous process; the posterior margins of the two portions are in contact and to a certain extent united, slight intervals being left for the passage of small vessels. Each consists of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the lamina above, some distance from its inferior margin, and to the posterior surface and upper margin of the lamina below. In the cervical region the ligaments are thin, but broad and long; they are thicker in the thoracic region, and thickest in the lumbar region. Their marked elasticity serves to preserve the upright posture, and to assist the vertebral column in resuming it after flexion.

disc (cut)

The Supraspinal Ligament (*ligamentum supraspinale; supraspinous ligament*) (Fig. 424).—The supraspinal ligament is a strong fibrous cord, which connects together the apices of the spinous processes from

FIG. 426.—Vertebral arches of three thoracic vertebrae viewed from the front.

the seventh cervical vertebra to the sacrum; at the points of attachment to the tips of the spinous processes fibrocartilage is developed in the ligament. It is thicker and broader in the lumbar than in the thoracic region, and intimately blended, in both situations, with the neighboring fascia. The most superficial fibres of this ligament extend over three or four vertebrae; those more deeply seated pass between two or three vertebrae; while the deepest connect the spinous processes of neighboring vertebrae. Between the spinous processes it is continuous with the interspinal ligaments. It is continued upward to the external occipital protuberance and median nuchal line, as the *ligamentum nuchae*.

The Ligamentum Nuchae.—The *ligamentum nuchae* is a fibrous membrane, which, in the neck, represents the supraspinal ligaments of the lower vertebrae. It extends from the external occipital protuberance and median nuchal line to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the posterior tubercle of the atlas, and to the spinous processes of the cervical vertebrae, and forms a septum between the muscles on either side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The Interspinal Ligaments (*ligamenta interspinalia; interspinous ligaments*) (Fig. 424).—The interspinal ligaments thin and membranous, connect adjoining spinous processes and extend from the root to the apex of each process. They meet the *ligamenta flava* in front and the supraspinal ligament behind. They are narrow and elongated in the thoracic region; broader, thicker, and quadrilateral in form in the lumbar region; and only slightly developed in the neck.

The Intertransverse Ligaments (*ligamenta intertransversaria*).—The intertransverse ligaments are interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the thoracic region they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

Movements.—The movements permitted in the vertebral column are: *flexion, extension, lateral movement, circumduction, and rotation.*

In **flexion**, or movement forward, the anterior longitudinal ligament is relaxed, and the intervertebral fibrocartilages are compressed in front; while the posterior longitudinal ligament, the ligamenta flava, and the inter- and supraspinal ligaments are stretched, as well as the posterior fibres of the intervertebral fibrocartilages. The interspaces between the laminae are widened, and the inferior articular processes glide upward, upon the superior articular processes of the subjacent vertebrae. Flexion is the most extensive of all the movements of the vertebral column, and is freest in the lumbar region.

In **extension**, or movement backward, an exactly opposite disposition of the parts takes place. This movement is limited by the anterior longitudinal ligament, and by the approximation of the spinous processes. It is freest in the cervical region.

In **lateral movement**, the sides of the intervertebral fibrocartilages are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments. This movement may take place in any part of the column, but is freest in the cervical and lumbar regions.

Circumduction is very limited, and is merely a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral fibrocartilages; this, although only slight between any two vertebrae, allows of a considerable extent of movement when it takes place in the whole length of the column, the front of the upper part of the column being turned to one or other side. This movement occurs to a slight extent in the cervical region, is freer in the upper part of the thoracic region, and absent in the lumbar region.

The extent and variety of the movements are influenced by the shape and direction of the articular surfaces. In the *cervical* region the upward inclination of the superior articular surfaces allows of free flexion and extension. Extension can be carried farther than flexion; at the upper end of the region it is checked by the locking of the posterior edges of the superior atlantal facets in the condyloid fossae of the occipital bone; at the lower end it is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic. Flexion is arrested just beyond the point where the cervical convexity is straightened; the movement is checked by the apposition of the projecting lower lips of the bodies of the vertebrae with the shelving surfaces on the bodies of the subjacent vertebrae. Lateral flexion and rotation are free in the cervical region; they are, however, always combined. The upward and medial inclinations of the superior articular surfaces impart a rotatory movement during lateral flexion, while pure rotation is prevented by the slight medial slope of these surfaces.

In the **thoracic region**, notably in its upper part, all the movements are limited in order to reduce interference with respiration to a minimum. The almost complete absence of an upward inclination of the superior articular surfaces prohibits any marked flexion, while extension is checked by the contact of the inferior articular margins with the laminae, and the contact of the spinous processes with one another. The mechanism between the seventh cervical and the first thoracic vertebrae, which limits extension of the cervical region, will also serve to limit flexion of the thoracic region when the neck is extended. Rotation is free in the thoracic region: the superior articular processes are segments of a cylinder whose axis is in the mid-ventral line of the vertebral bodies. The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum.

In the **lumbar region** flexion and extension are free. Flexion can be carried farther than extension, and is possible to just beyond the straightening of the lumbar curve; it is, therefore, greatest at the lowest part where the curve is sharpest. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebrae, and on this account a considerable amount of lateral flexion is permitted. For the same reason a slight amount of rotation can be carried out, but this is so soon checked by the interlocking of the articular surfaces that it is negligible.

The principal muscles which produce *flexion* are the Sternocleidomastoideus, Longus capitis, and Longus colli; the Scaleri; the abdominal muscles and the Psoas major. *Extension* is produced by the intrinsic muscles of the back, assisted in the neck by the Splenius, Semispinales dorsi and cervicis, and the Multifidus. *Lateral* motion is produced by the intrinsic muscles of the back by the Splenius, the Scaleri, the Quadratus lumborum, and the Psoas major, the muscles of one side only acting; and *rotation* by the action of the following muscles of one side only, viz., the Sternocleidomastoideus, the Longus capitis, the Scaleri, the Multifidus, the Semispinalis capitis, and the abdominal muscles.

II. Articulation of the Atlas with the Epistropheus or Axis (*Articulatio Atlantoepistrophica*).

The articulation of the atlas with the axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between

the odontoid process of the axis and the ring formed by the anterior arch and the transverse ligament of the atlas (see Fig. 429); here there are two joints: one between the posterior surface of the anterior arch of the atlas and the front of the odontoid process; the other between the anterior surface of the ligament and the back of the process. Between the articular processes of the two bones there is on either side an arthrodial or gliding joint. The ligaments connecting these bones are:

Two Articular Capsules.

The Posterior Atlantoaxial.

The Anterior Atlantoaxial.

The Transverse.

The Articular Capsules (*capsulae articulares; capsular ligaments*).—The articular capsules are thin and loose, and connect the margins of the lateral masses of the atlas with those of the posterior articular surfaces of the axis. Each is strengthened at its posterior and medial part by an *accessory ligament*, which is attached below to the body of the axis near the base of the odontoid process, and above to the lateral mass of the atlas near the transverse ligament.

FIG. 427.—Anterior atlantooccipital membrane and atlantoaxial ligament.

The Anterior Atlantoaxial Ligament (Fig. 427).—This ligament is a strong membrane, fixed, *above*, to the lower border of the anterior arch of the atlas; *below*, to the front of the body of the axis. It is strengthened in the middle line by a rounded cord, which connects the tubercle on the anterior arch of the atlas to the body of the axis, and is a continuation upward of the anterior longitudinal ligament. The ligament is in relation, in front, with the *Longi capitis*.

The Posterior Atlantoaxial Ligament (Fig. 428).—This ligament is a broad, thin membrane attached, *above*, to the lower border of the posterior arch of the atlas; *below*, to the upper edges of the laminae of the axis. It supplies the place of the *ligamenta flava*, and is in relation, *behind*, with the *Obliqui capitis inferiores*.

The Transverse Ligament of the Atlas (*ligamentum transversum atlantis*) (Figs. 429, 430, 431).—The transverse ligament of the atlas is a thick, strong band, which arches across the ring of the atlas, and retains the odontoid process in contact with the anterior arch. It is concave in front, convex behind, broader and thicker in

the middle than at the ends, and firmly attached on either side to a small tubercle on the medial surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus (*crus superius*) is prolonged upward, and another (*crus inferius*) downward, from the superficial or posterior fibres of the ligament. The

former is attached to the basilar part of the occipital bone, in close relation with the membrana tectoria; the latter is fixed to the posterior surface of the body of the axis; hence, the whole ligament is named the **cruciate ligament of the atlas**. The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the medulla spinalis

FIG. 429.—Articulation between odontoid process and atlas.

and its membranes and the accessory nerves; the anterior and smaller contains the odontoid process. The neck of the odontoid process is constricted where it is embraced posteriorly by the transverse ligament, so that this ligament suffices to retain the odontoid process in position after all the other ligaments have been divided.

Synovial Membranes.—There is a synovial membrane for each of the four joints; the joint cavity between the odontoid process and the transverse ligament is often continuous with those of the atlantoöccipital articulations.

The opposed articular surfaces of the atlas and axis are not reciprocally curved; both surfaces are convex in their long axes. When, therefore, the upper facet glides forward on the lower it

Movements.—This joint allows the rotation of the atlas (and, with it, the skull) upon the axis, the extent of rotation being limited by the alar ligaments.

also descends; the fibres of the articular capsule are relaxed in a vertical direction, and will then permit of movement in an antero-posterior direction. By this means a shorter capsule suffices and the strength of the joint is materially increased.¹

The principal muscles by which these movements are produced are the Sternocleidomastoideus and Semispinalis capitis of one side, acting with the Longus capitis, Splenius, Longissimus capitis, Rectus capitis posterior major, and Obliqui capitis superior and inferior of the other side.

III. Articulations of the Vertebral Column with the Cranium.

The ligaments connecting the vertebral column with the cranium may be divided into two sets: those uniting the atlas with the occipital bone, and those connecting the axis with the occipital bone.

Articulation of the Atlas with the Occipital Bone (*articulatio atlantoöccipitalis*).

—The articulation between the atlas and the occipital bone consists of a pair of condyloid joints. The ligaments connecting the bones are:

Two Articular Capsules.

The Anterior Atlantoöccipital membrane.

The Posterior Atlantoöccipital membrane.

Two Lateral Atlantoöccipital.

The Articular Capsules (*capsulae articulares; capsular ligaments*).—The articular capsules surround the condyles of the occipital bone, and connect them with the articular processes of the atlas: they are thin and loose.

The Anterior Atlantoöccipital Membrane (*membrana atlantoöccipitalis anterior; anterior atlantoöccipital ligament*) (Fig. 427).—The anterior atlantoöccipital membrane is broad and composed of densely woven fibres, which pass between the anterior margin of the foramen magnum above, and the upper border of the anterior arch of the atlas below; laterally, it is continuous with the articular capsules; in front, it is strengthened in the middle line by a strong, rounded cord, which connects the basilar part of the occipital bone to the tubercle on the anterior arch of the atlas. This membrane is in relation in *front* with the Recti capitis anteriores, *behind* with the alar ligaments.

The Posterior Atlantoöccipital Membrane (*membrana atlantoöccipitalis posterior; posterior atlantoöccipital ligament*) (Fig. 428).—The posterior atlantoöccipital membrane, broad but thin, is connected above, to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. On either side this membrane is defective below, over the groove for the vertebral artery, and forms with this groove an opening for the entrance of the artery and the exit of the suboccipital nerve. The free border of the membrane, arching over the artery and nerve, is sometimes ossified. The membrane is in relation, *behind*, with the Recti capitis posteriores minores and Obliqui capitis superiores; in *front*, with the dura mater of the vertebral canal, to which it is intimately adherent.

The Lateral Ligaments.—The lateral ligaments are thickened portions of the articular capsules, reinforced by bundles of fibrous tissue, and are directed obliquely upward and medialward; they are attached above to the jugular processes of the occipital bone, and below, to the bases of the transverse processes of the atlas.

¹ Corner ("The Physiology of the Atlanto-axial Joints," *Journal of Anatomy and Physiology*, vol. xli) states that the movements which take place at these articulations are of a complex nature. The first part of the movement is an eccentric or asymmetrical one; the atlanto-axial joint of the side to which the head is moved is fixed, or practically fixed, by the muscles of the neck, and forms the centre of the movement, while the opposite atlantal facet is carried downward and forward on the corresponding axial facet. The second part of the movement is centric and symmetrical, the odontoid process forming the axis of the movement.

Synovial Membranes.—There are two synovial membranes: one lining each of the articular capsules. The joints frequently communicate with that between the posterior surface of the odontoid process and the transverse ligament of the atlas.

Movements.—The movements permitted in this joint are (a) flexion and extension, which give rise to the ordinary forward and backward nodding of the head, and (b) slight lateral motion to one or other side. *Flexion* is produced mainly by the action of the Longi capitis and Recti capitis anteriores; *extension* by the Recti capitis posteriores major and minor, the Obliquus superior, the Semispinalis capitis, Splenius capitis, Sternocleidomastoideus, and upper fibres of the Trapezius. The Recti laterales are concerned in the *lateral movement*, assisted by the Trapezius, Splenius capitis, Semispinalis capitis, and the Sternocleidomastoideus of the same side, all acting together.

Ligaments Connecting the Axis with the Occipital Bone.—

The Membrana Tectoria. Two Alar. The Apical Odontoid.

The Membrana Tectoria (*occipitoaxial ligament*) (Figs. 430, 431).—The membrana tectoria is situated within the vertebral canal. It is a broad, strong band, which covers the odontoid process and its ligaments, and appears to be a prolongation upward of the posterior longitudinal ligament of the vertebral column. It is fixed, below, to the posterior surface of the body of the axis, and, expanding as it ascends, is attached to the basilar groove of the occipital bone, in front of the foramen magnum, where it blends with the cranial dura mater. Its anterior surface is in relation with the transverse ligament of the atlas, and its posterior surface with the dura mater.

The Alar Ligaments (*ligamenta alaria; odontoid ligaments*) (Fig. 430).—The alar ligaments are strong, rounded cords, which arise one on either side of the upper part of the odontoid process, and, passing obliquely upward and lateralward, are inserted into the rough depressions on the medial sides of the condyles of the occipital bone. In the triangular interval between these ligaments is another fibrous cord, the *apical odontoid ligament* (Fig. 431), which extends from the tip of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior atlantooccipital membrane and superior crus of the transverse ligament of the atlas. It is regarded as a rudimentary intervertebral fibrocartilage, and in it traces of the notochord may persist. The alar ligaments limit rotation of the cranium and therefore receive the name of *check ligaments*.

In addition to the ligaments which unite the atlas and axis to the skull, the *ligamentum nuchae* (page 387) must be regarded as one of the ligaments connecting the vertebral column with the cranium.

Applied Anatomy.—The ligaments which unite the component parts of the vertebral column together are so strong, and the bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, except in the upper part of the neck, rarely occurs unless accompanied by fracture. Dislocation of the occipital bone from the atlas has been recorded only in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common; it is the mode in which death is produced in many cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

IV. Articulation of the Mandible (Articulatio Mandibularis; Temporomandibular Articulation).

This is a ginglymo-arthrodial joint; the parts entering into its formation on either side are: the anterior part of the mandibular fossa of the temporal bone and the articular tubercle above; and the condyle of the mandible below. The ligaments of the joint are the following:

The Articular Capsule.	The Sphenomandibular.
The Temporomandibular.	The Articular Disk.
The Stylomandibular.	

The Articular Capsule (*capsula articularis*; *capsular ligament*).—The articular capsule is a thin, loose envelope, attached above to the circumference of the mandibular fossa and the articular tubercle immediately in front; below, to the neck of the condyle of the mandible.

FIG. 432.—Articulation of the mandible. Lateral aspect.

The Temporomandibular Ligament (*ligamentum temporomandibulare*; *external lateral ligament*) (Fig. 432).—The temporomandibular ligament consists of two

FIG. 433.—Articulation of the mandible. Medial aspect.

FIG. 434.—Sagittal section of the articulation of the mandible.

short, narrow fasciculi, one in front of the other, attached, above, to the lateral surface of the zygomatic arch and to the tubercle on its lower border; below,

to the lateral surface and posterior border of the neck of the mandible. It is broader above than below, and its fibres are directed obliquely downward and backward. It is covered by the parotid gland, and by the integument.

The Sphenomandibular Ligament (*ligamentum sphenomandibulare*; *internal lateral ligament*) (Fig. 433).—The sphenomandibular ligament is a flat, thin band which is attached above to the spina angularis of the sphenoid bone, and, becoming broader as it descends, is fixed to the lingula of the mandibular foramen. Its lateral surface is in relation, above, with the Pterygoideus externus; lower down, it is separated from the neck of the condyle by the internal maxillary vessels; still lower, the inferior alveolar vessels and nerve and a lobule of the parotid gland lie between it and the ramus of the mandible. Its medial surface is in relation with the Pterygoideus internus.

The Articular Disk (*discus articularis*; *interarticular fibrocartilage*; *articular meniscus*) (Fig. 434).—The articular disk is a thin, oval plate, placed between the condyle of the mandible and the mandibular fossa. Its upper surface is concavo-convex from before backward, to accommodate itself to the form of the mandibular fossa and the articular tubercle. Its under surface, in contact with the condyle, is concave. Its circumference is connected to the articular capsule; and in front to the tendon of the Pterygoideus externus. It is thicker at its periphery, especially behind, than at its centre. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. It divides the joint into two cavities, each of which is furnished with a synovial membrane.

The Synovial Membranes.—The synovial membranes, two in number, are placed one above, and the other below, the articular disk. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the mandibular fossa and articular tubercle on to the upper surface of the disk. The lower one passes from the under surface of the disk to the neck of the condyle, being prolonged a little farther downward behind than in front. The articular disk is sometimes perforated in its centre, and the two cavities then communicate with each other.

The Stylomandibular Ligament (*ligamentum stylomandibulare*); *stylomaxillary ligament* (Fig. 433).—The stylomandibular ligament is a specialized band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible, between the Masseter and Pterygoideus internus. This ligament separates the parotid from the submaxillary gland, and from its deep surface some fibres of the Styloglossus take origin. Although classed among the ligaments of the temporomandibular joint, it can only be considered as accessory to it.

The **nerves** of the temporomandibular joint are derived from the auriculotemporal and masseteric branches of the mandibular nerve, the **arteries** from the superficial temporal branch of the external carotid.

Movements.—The movements permitted in this articulation are extensive. Thus, the mandible may be depressed or elevated, or carried forward or backward; a slight amount of side-to-side movement is also permitted. It must be borne in mind that there are two distinct joints in this articulation—one between the condyle and the articular disk, and another between the disk and the mandibular fossa. When the mouth is but slightly opened, as during ordinary conversation, the movement is confined to the lower of the two joints. On the other hand, when the mouth is opened more widely, both joints are concerned in the movement; in the lower joint the movement is of a hinge-like character, the condyle moving around a transverse axis on the disk, while in the upper joint the movement is of a gliding character, the disk, together with the condyle, gliding forward on to the articular tubercle, around an axis which passes through the mandibular foramina. These two movements take place simultaneously, the condyle and disk move forward on the eminence, and at the same time the condyle revolves on the disk. In shutting the mouth the reverse action takes place; the disk glides back, carrying the condyle with it, and this at the same time moves back to its former position. When the mandible is carried horizontally forward, as in protruding the lower incisor teeth in front of the upper, the movement takes place principally in the upper joint, the disk and the condyle gliding forward on the mandibular fossa

and articular tubercle. The grinding or chewing movement is produced by one condyle, with its disk, gliding alternately forward and backward, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on the disk. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

The mandible is *depressed* by its own weight, assisted by the Platysma, the Digastricus, the Mylohyoideus, and the Geniohyoideus. It is *elevated* by the Masseter, Pterygoideus internus, and the anterior part of the Temporalis. It is drawn *forward* by the simultaneous action of the Pterygoidei internus and externus, the superficial fibres of the Masseter and the anterior fibres of the Temporalis; and *backward* by the deep fibres of the Masseter and the posterior fibres of the Temporalis. The grinding movement is caused by the alternate action of the Pterygoidei of either side.

Applied Anatomy.—The mandible is dislocated only in one direction, viz., forward. The accident is caused by violence or by muscular action. When the mouth is open, the condyle is situated on the articular tubercle, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forward into the infratemporal fossa. The displacement may be unilateral or bilateral. Reduction is accomplished by depressing the jaw with the thumbs placed on the last molar teeth, and at the same time elevating the chin. The downward pressure overcomes the spasm of the Masseter, Temporalis, and Pterygoideus internus, and elevation of the chin throws the condyle backward; the above-mentioned muscles then draw the condyle back into its normal position.

In close relation to the condyle of the mandible are the external acoustic meatus and the tympanic cavity; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to them; or on the other hand inflammation of the tympanic cavity may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. The joint is also occasionally the seat of osteoarthritis, causing great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the mandible, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

V. Costovertebral Articulations (Articulationes Costovertebrales).

The articulations of the ribs with the vertebral column may be divided into two sets, one connecting the heads of the ribs with the bodies of the vertebræ, another uniting the necks and tubercles of the ribs with the transverse processes.

1. **Articulations of the Heads of the Ribs** (*articulationes capitulorum; costocentral articulations*) (Fig. 435).—These constitute a series of gliding or arthrodial joints, and are formed by the articulation of the heads of the typical ribs with the facets on the contiguous margins of the bodies of the thoracic vertebræ and with the intervertebral fibrocartilages between them; the first, tenth, eleventh, and twelfth ribs each articulate with a single vertebra. The ligaments of the joints are:

The Articular Capsule.

The Radiate.

The Interarticular.

The Articular Capsule (*capsula articularis; capsular ligament*).—The articular capsule surrounds the joint, being composed of short, strong fibres, connecting the head of the rib with the circumference of the articular cavity formed by the intervertebral fibrocartilage and the adjacent vertebræ. It is most distinct at the upper and lower parts of the articulation; some of its upper fibres pass through the intervertebral foramen to the back of the intervertebral fibrocartilage, while its posterior fibres are continuous with the ligament of the neck of the rib.

The Radiate Ligament (*ligamentum capituli costae radiatum; anterior costovertebral or stellate ligament*).—The radiate ligament connects the anterior part of the head of each rib with the side of the bodies of two vertebræ, and the intervertebral fibrocartilage between them. It consists of three fasciculi, which are attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fasciculus ascends and is connected with the body of the vertebra above; the inferior one descends to the body of the vertebra below; the middle one, the smallest and least distinct, is horizontal and is attached to the intervertebral fibrocartilage. The radiate ligament is in relation, in *front*, with the thoracic

ganglia of the sympathetic trunk, the pleura, and, on the right side, with the azygos vein; behind, with the interarticular ligament and synovial membranes.

In the case of the first rib, this ligament is not divided into three fasciculi, but its fibres are attached to the body of the last cervical vertebra, as well as to that of the first thoracic. In the articulations of the heads of the tenth, eleventh, and twelfth ribs, each of which articulates with a single vertebra, the triradiate arrangement does not exist; but the fibres of the ligament in each case are connected to the vertebra above, as well as to that with which the rib articulates.

LAPSE SYNOVIAL CAVITY

FIG. 435.—Costovertebral articulations. Anterior view

The Interarticular Ligament (*ligamentum capituli costae interarticulare*; *interarticular ligament*).—The interarticular ligament is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downward, attached by one extremity to the crest separating the two articular facets on the head of the rib, and by the other to the intervertebral fibrocartilage; it divides the joint into two cavities. In the joints of the first, tenth, eleventh, and twelfth ribs, the interarticular ligament does not exist; consequently, there is but one cavity in each of these articulations. This ligament is the homologue of the *ligamentum conjugale* present in some mammals, and uniting the heads of opposite ribs, across the back of the intervertebral fibrocartilage.

Synovial Membranes.—There are two synovial membranes in each of the articulations where an interarticular ligament exists, one above and one below this structure; but only one in those joints where there are single cavities.

2. Costotransverse Articulations (*articulationes costotransversariae*) (Fig. 436).—The articular portion of the tubercle of the rib forms with the articular surface on the adjacent transverse process an arthrodiar joint.

In the eleventh and twelfth ribs this articulation is wanting.

The ligaments of the joint are:

- | | |
|--|--------------------------------------|
| The Articular Capsule. | The Posterior Costotransverse. |
| The Anterior Costotransverse. | The Ligament of the Neck of the Rib. |
| The Ligament of the Tubercle of the Rib. | |

The Articular Capsule (*capsula articularis*; *capsular ligament*).—The articular capsule is a thin membrane attached to the circumferences of the articular surfaces, and lined by a synovial membrane.

Liga

Liga

FIG. 436.—Costotransverse articulation. Seen from above.

FIG. 437.—Section of the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper with the flattened facets on the lower transverse processes.

The Anterior Costotransverse Ligament (*ligamentum costotransversarium anterius*; *anterior superior ligament*).—The anterior costotransverse ligament is attached below to the sharp crest on the upper border of the neck of the rib, and passes obliquely upward and lateralward to the lower border of the transverse process immediately above. It is in relation, in front, with the intercostal vessels and nerves; its medial border is thickened and free, and bounds an aperture which transmits the posterior branches of the intercostal vessels and nerves; its lateral border is continuous with a thin aponeurosis, which covers the *Intercostalis externus*.

The first rib has no anterior costotransverse ligament. A band of fibres, the **lumbocostal ligament**, in series with the anterior costotransverse ligaments, connects the neck of the twelfth rib to the base of the transverse process of the first lumbar vertebra; it is merely a thickened portion of the posterior layer of the *lumbodorsal fascia*.

The Posterior Costotransverse Ligament (*ligamentum costotransversarium posterius*).—The posterior costotransverse ligament is a feeble band which is attached below to the neck of

the rib and passes upward and medialward to the base of the transverse process and lateral border of the inferior articular process of the vertebra above.

The Ligament of the Neck of the Rib (*ligamentum colli costae; middle costotransverse or interosseous ligament*).—The ligament of the neck of the rib consists of short but strong fibres, connecting the rough surface on the back of the neck of the rib with the anterior surface of the adjacent transverse process. A rudimentary ligament may be present in the case of the eleventh and twelfth ribs.

The Ligament of the Tubercle of the Rib (*ligamentum tuberculi costae; posterior costotransverse ligament*).—The ligament of the tubercle of the rib is a short but thick and strong fasciculus, which passes obliquely from the apex of the transverse process to the rough non-articular portion of the tubercle of the rib. The ligaments attached to the upper ribs ascend from the transverse processes; they are shorter and more oblique than those attached to the inferior ribs, which descend slightly.

Movements.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the radiate and interarticular ligaments that only slight gliding movements of the articular surfaces on one another can take place. Similarly, the strong ligaments binding the necks and tubercles of the ribs to the transverse processes limit the movements of the costotransverse joints to slight gliding, the nature of which is determined by the shape and direction of the articular surfaces (Fig. 437). In the upper six ribs the articular surfaces on the tubercles are oval in shape and convex from above downward; they fit into corresponding concavities on the *anterior surfaces* of the transverse processes, so that upward and downward movements of the tubercles are associated with rotation of the rib neck on its long axis. In the seventh, eighth, ninth, and tenth ribs the articular surfaces on the tubercles are flat, and are directed obliquely downward, medialward, and backward. The surfaces with which they articulate are placed on the *upper margins* of the transverse processes; when, therefore, the tubercles are drawn up they are at the same time carried backward and medialward. The two joints, costocentral and costotransverse, move simultaneously and in the same directions, the total effect being that the neck of the rib moves as if on a single joint, of which the costocentral and costotransverse articulations form the ends. In the upper six ribs the neck of the rib moves but slightly upward and downward; its chief movement is one of rotation around its own long axis, rotation backward being associated with depression, rotation forward with elevation. In the seventh, eighth, ninth, and tenth ribs the neck of the rib moves upward, backward, and medialward, or downward, forward, and lateralward; very slight rotation accompanies these movements.

VI. Sternocostal Articulations (Articulationes Sternocostales; Costosternal Articulations) (Fig. 438)

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is directly united with the sternum, and which is, therefore, a synarthrodial articulation. The ligaments connecting them are:

The Articular Capsules.

The Interarticular Sternocostal.

The Radiate Sternocostal.

The Costoxiphoid.

The Articular Capsules (*capsulae articulares; capsular ligaments*).—The articular capsules surround the joints between the cartilages of the true ribs and the sternum. They are very thin, intimately blended with the radiate sternocostal ligaments, and strengthened at the upper and lower parts of the articulations by a few fibres, which connect the cartilages to the side of the sternum.

The Radiate Sternocostal Ligaments (*ligamenta sternocostalia radiata; chondrosternal or sternocostal ligaments*).—These ligaments consist of broad and thin membranous bands that radiate from the front and back of the sternal ends of the cartilages of the true ribs to the anterior and posterior surfaces of the sternum. They are composed of fasciculi which pass in different directions. The **superior fasciculi** ascend obliquely, the **inferior fasciculi** descend obliquely, and the **middle fasciculi** run horizontally. The superficial fibres are the longest; they intermingle with the fibres of the ligaments above and below them, with those of the opposite

side, and in front with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane (*membrana sterni*) which envelopes the sternum. This is more distinct at the lower than at the upper part of the bone.

The Interarticular Sternocostal Ligament (*ligamentum sternocostale interarticulare; interarticular chondrosternal ligament*).—This ligament is found constantly only between the second costal cartilages and the sternum. The cartilage of the *second*

*The synovial cavities are exposed by
a coronal section of the sternum and cartilages*

as with

*ment and
branes*

*synovial
rane*

FIG. 438.—Sternocostal and interchondral articulations. Anterior view.

rib is connected with the sternum by means of an interarticular ligament, attached by one end to the cartilage of the rib, and by the other to the fibrocartilage which unites the manubrium and body of the sternum. This articulation is provided with two synovial membranes. Occasionally the cartilage of the *third rib* is connected with the first and second pieces of the body of the sternum by an interarticular ligament. Still more rarely, similar ligaments are found in the other four

joints of the series. - In the lower two the ligament sometimes completely obliterates the cavity, so as to convert the articulation into an amphiarthrosis.

The Costoxiphoid Ligaments (*ligamenta costoxiphoidea; chondroxiphoid ligaments*). - These ligaments connect the anterior and posterior surfaces of the seventh costal cartilage, and sometimes those of the sixth, to the front and back of the xiphoid process. They vary in length and breadth in different subjects; those on the back of the joint are less distinct than those in front.

Synovial Membranes.—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the manubrium. There are two in the articulation of the second costal cartilage and generally one in each of the other joints; but those of the sixth and seventh sternocostal joints are sometimes absent; where an interarticular ligament is present, there are two synovial cavities. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes apparently disappear. In old age, the cartilages of most of the ribs become continuous with the sternum, and the joint cavities are consequently obliterated.

Movements.—Slight gliding movements are permitted in the sternocostal articulations.

Interchondral Articulations (*articulationes interchondrales; articulations of the cartilages of the ribs with each other*) (Fig. 438).—The contiguous borders of the sixth, seventh, and eighth, and sometimes those of the ninth and tenth, costal cartilages articulate with each other by small, smooth, oblong facets. Each articulation is enclosed in a thin articular capsule, lined by synovial membrane and strengthened laterally and medially by ligamentous fibres (*interchondral ligaments*) which pass from one cartilage to the other. Sometimes the fifth costal cartilages, more rarely the ninth and tenth, articulate by their lower borders with the adjoining cartilages by small oval facets; more frequently the connection is by a few ligamentous fibres.

Costochondral Articulations.—The lateral end of each costal cartilage is received into a depression in the sternal end of the rib, and the two are held together by the periosteum.

VII. Articulation of the Manubrium and Body of the Sternum.

The manubrium is united to the body of the sternum either by an amphiarthrodial joint—a piece of fibrocartilage connecting the segments—or by a diarthrodial joint, in which the articular surface of each bone is clothed with a lamina of cartilage. In the latter case, the cartilage covering the body is continued without interruption on to the cartilages of the facets for the second ribs. Rivington found the diarthrodial form of joint in about one-third of the specimens examined by him, Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Rivington's opinion, from the amphiarthrodial form, by absorption. The diarthrodial joint seems to have no tendency to ossify, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. The two segments are further connected by anterior and posterior intersternal ligaments consisting of longitudinal fibres.

Mechanism of the Thorax.—Each rib possesses its own range and variety of movements, but the movements of all are combined in the respiratory excursions of the thorax. Each rib may be regarded as a lever the fulcrum of which is situated immediately outside the costotransverse articulation, so that when the body of the rib is elevated the neck is depressed and *vice versa*; from the disproportion in length of the arms of the lever a slight movement at the vertebral end of the rib is greatly magnified at the anterior extremity.

The anterior ends of the ribs lie on a lower plane than the posterior; when therefore the body of the rib is elevated the anterior extremity is thrust also forward. Again, the middle of the body of the rib lies in a plane below that passing through the two extremities, so that when the body is elevated relatively to its ends it is at the same time carried outward from the median plane of the thorax. Further, each rib forms the segment of a curve which is greater than that of the rib immediately above, and therefore the elevation of a rib increases the transverse diameter of the thorax in the plane to which it is raised. The modifications of the rib movements at their vertebral ends have already been described (page 399). Further modifications result from the

attachments of their anterior extremities, and it is convenient therefore to consider separately the movements of the ribs of the three groups—vertebrosternal, vertebrochondral, and vertebral.

FIG. 439.—Lateral view of first and seventh ribs in position, showing the movements of the sternum and ribs in A, ordinary expiration; B, quiet inspiration; C, deep inspiration.

in this way the transverse thoracic diameter is increased. Elevation of the third, fourth, fifth, and sixth ribs raises and thrusts forward their anterior extremities, the greater part of the movement being effected by the rotation of the rib neck backward. The thrust of the anterior extremities carries forward and upward the body of the sternum, which moves on the joint

Vertebrosteral Ribs (Figs. 439, 440).—The first rib differs from the others of this group in that its attachment to the sternum is a rigid one; this is counterbalanced to some extent by the fact that its head possesses no interarticular ligament, and is therefore more movable. The first pair of ribs with the manubrium sterni move as a single piece, the anterior portion being elevated by rotatory movements at the vertebral extremities. In normal quiet respiration the movement of this arc is practically nil; when it does occur the anterior part is raised and carried forward, increasing the antero-posterior and transverse diameters of this region of the chest. The movement of the second rib is also slight in normal respiration, as its anterior extremity is fixed to the manubrium, and prevented therefore from moving upward. The sternocostal articulation, however, allows the middle of the body of the rib to be drawn up, and

FIG. 440.—Diagram showing the axes of movement (A B and C D) of a vertebrosteral rib. The interrupted lines indicate the position of the rib in inspiration.

FIG. 441.—Diagram showing the axis of movement (A B) of a vertebrochondral rib. The interrupted lines indicate the position of the rib in inspiration.

between it and the manubrium, and thus the antero-posterior thoracic diameter is increased. This movement is, however, soon arrested, and the elevating force is then expended in raising the middle part of the body of the rib and everting its lower border; at the same time the

costochondral angle is opened out. By these latter movements a considerable increase in the transverse diameter of the thorax is effected.

Vertebrochondral Ribs (Fig. 441).—The seventh rib is included with this group, as it conforms more closely to their type. While the movements of these ribs assist in enlarging the thorax for respiratory purposes, they are also concerned in increasing the upper abdominal space for viscera displaced by the action of the Diaphragma. The costal cartilages articulate with one another, so that each pushes up that above it, the final thrust being directed to pushing forward and upward the lower end of the body of the sternum. The amount of elevation of the anterior extremities is limited on account of the very slight rotation of the rib neck. Elevation of the shaft is accompanied by an outward and backward movement; the outward movement everts the anterior end of the rib and opens up the subcostal angle, while the backward movement pulls back the anterior extremity and counteracts the forward thrust due to its elevation; this latter is most noticeable in the lower ribs, which are the shortest. The total result is a considerable increase in the transverse and a diminution in the median antero-posterior diameter of the upper part of the abdomen; at the same time, however, the lateral antero-posterior diameters of the abdomen are increased.

Vertebral Ribs.—Since these ribs have free anterior extremities and only costocentral articulations with no interarticular ligaments, they are capable of slight movements in all directions. When the other ribs are elevated these are depressed and fixed to form points of action for the Diaphragma.

FIG. 442.—Articulations of pelvis and hip. Anterior view.

VIII. Articulation of the Vertebral Column with the Pelvis.

The ligaments connecting the fifth lumbar vertebra with the sacrum are similar to those which join the movable segments of the vertebral column with each other—viz.: 1. The continuation downward of the anterior and posterior longitudinal ligaments. 2. The intervertebral fibrocartilage, connecting the body of the fifth lumbar to that of the first sacral vertebra and forming an amphiarthrodial joint. 3. Ligamenta flava, uniting the laminae of the fifth lumbar vertebra with those of the first sacral. 4. Capsules connecting the articular processes and forming a double arthrodia. 5. Inter- and supraspinal ligaments.

On either side an additional ligament, the **iliolumbar**, connects the pelvis with the vertebral column.

The Iliolumbar Ligament (*ligamentum iliolumbale*) (Fig. 442).—The iliolumbar ligament is attached above to the lower and front part of the transverse process of the fifth lumbar vertebra. It radiates as it passes lateralward and is attached by two main bands to the pelvis. The lower bands run to the base of the sacrum, blending with the anterior sacroiliac ligament; the upper is attached to the crest of the ilium immediately in front of the sacroiliac articulation, and is continuous above with the lumbodorsal fascia. In *front*, it is in relation with the Psoas major; *behind*, with the muscles occupying the vertebral groove; *above*, with the Quadratus lumborum.

IX. Articulations of the Pelvis.

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those uniting the sacrum and coccyx. 4. Those between the two pubic bones.

1. **Sacroiliac Articulation** (*articulatio sacroiliaca*).—The sacroiliac articulation is an amphiarthrodial joint, formed between the auricular surfaces of the sacrum and the ilium. The articular surface of each bone is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. These cartilaginous plates are in close contact with each other, and to a certain extent are united together by irregular patches of softer fibrocartilage, and at their upper and posterior part by fine interosseous fibres. In a considerable part of their extent, especially in advanced life, they are separated by a space containing a synovia-like fluid, and hence the joint presents the characteristics of a diarthrosis. The ligaments of the joint are:

The Anterior Sacroiliac.

The Posterior Sacroiliac.

The Interosseous.

The Anterior Sacroiliac Ligament (*ligamentum sacroiliacum anterius*) (Fig. 442).—The anterior sacroiliac ligament consists of numerous thin bands, which connect the anterior surface of the lateral part of the sacrum to the margin of the auricular surface of the ilium and to the preauricular sulcus.

The Posterior Sacroiliac Ligament (*ligamentum sacroiliacum posterius*) (Fig. 443).—The posterior sacroiliac ligament is situated in a deep depression between the sacrum and ilium behind; it is strong and forms the chief bond of union between the bones. It consists of numerous fasciculi, which pass between the bones in various directions. The upper part (**short posterior sacroiliac ligament**) is nearly horizontal in direction, and passes from the first and second transverse tubercles on the back of the sacrum to the tuberosity of the ilium. The lower part (**long posterior sacroiliac ligament**) is oblique in direction; it is attached by one extremity to the third transverse tubercle of the back of the sacrum, and by the other to the posterior superior spine of the ilium.

The Interosseous Sacroiliac Ligament (*ligamentum sacroiliacum interosseum*).—This ligament lies deep to the posterior ligament, and consists of a series of short, strong fibres connecting the tuberosities of the sacrum and ilium.

2. Ligaments Connecting the Sacrum and Ischium (Fig. 443).

The Sacrotuberous.

The Sacrospinous.

The Sacrotuberous Ligament (*ligamentum sacrotuberosum*; *great or posterior sacrosciatic ligament*).—The sacrotuberous ligament is situated at the lower and back part of the pelvis. It is flat, and triangular in form; narrower in the middle than at the ends; attached by its broad base to the posterior inferior spine of the

ilium, to the fourth and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downward, forward, and lateralward, it becomes narrow and thick, but at its insertion into the inner margin of the tuberosity of the ischium, it increases in breadth, and is prolonged forward along the inner margin of the ramus, as the **falciform process**, the free concave edge of which gives attachment to the obturator fascia; one of its surfaces is turned toward the perineum, the other toward the Obturator internus.

The lower border of the ligament is directly continuous with the tendon of origin of the long head of the Biceps femoris, and by many is believed to be the proximal end of this tendon, cut off by the projection of the tuberosity of the ischium.

FIG. 443.—Articulations of pelvis and hip. Posterior view

Relations.—The posterior surface of this ligament gives origin, by its whole extent, to the *Glutæus maximus*. Its anterior surface is in part united to the sacrospinous ligament. Its upper border forms, above, the posterior boundary of the greater sciatic foramen, and, below, the posterior boundary of the lesser sciatic foramen. Its lower border forms part of the boundary of the perineum. It is pierced by the coccygeal nerve and the coccygeal branch of the inferior gluteal artery.

The Sacrospinous Ligament (*ligamentum sacrospinosum*; *small or anterior sacro-sciatic ligament*).—The sacrospinous ligament is thin, and triangular in form; it is attached by its apex to the spine of the ischium, and medially, by its broad base, to the lateral margins of the sacrum and coccyx, in front of the sacrotuberous ligament with which its fibres are intermingled.

Relations.—It is in relation, anteriorly, with the Coccygeus muscle, to which it is closely connected; posteriorly, it is covered by the sacrotuberous ligament, and crossed by the internal pudendal vessels and nerve. Its upper border forms the lower boundary of the greater sciatic foramen; its lower border, part of the margin of the lesser sciatic foramen.

These two ligaments convert the sciatic notches into foramina. The **greater sciatic foramen** is bounded, in *front* and *above*, by the posterior border of the hip bone; *behind*, by the sacrotuberous ligament; and *below*, by the sacrospinous ligament. It is partially filled up, in the recent state, by the Piriformis which leaves the pelvis through it. Above this muscle, the superior gluteal vessels and nerve emerge from the pelvis; and below it, the inferior gluteal vessels and nerve, the internal pudendal vessels and nerve, the sciatic and posterior femoral cutaneous nerves, and the nerves to the Obturator internus and Quadratus femoris make their exit from the pelvis. The **lesser sciatic foramen** is bounded, in *front*, by the tuberosity of the ischium; *above*, by the spine of the ischium and sacrospinous ligament; *behind*, by the sacrotuberous ligament. It transmits the tendon of the Obturator internus, its nerve, and the internal pudendal vessels and nerve.

3. Sacrococcygeal Symphysis (*symphysis sacrococcygea; articulation of the sacrum and coccyx*).—This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum, and the base of the coccyx. It is homologous with the joints between the bodies of the vertebræ, and is connected by similar ligaments. They are:

The Anterior Sacrococcygeal.	The Lateral Sacrococcygeal.
The Posterior Sacrococcygeal.	The Interposed Fibrocartilage.
The Interarticular.	

The Anterior Sacrococcygeal Ligament (*ligamentum sacrococcygeum anterius*).—This consists of a few irregular fibres, which descend from the anterior surface of the sacrum to the front of the coccyx, blending with the periosteum.

The Posterior Sacrococcygeal Ligament (*ligamentum sacrococcygeum posterius*).—This is a flat band, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal, and is divisible into a short deep portion and a longer superficial part. It is in relation, behind, with the Gluteus maximus.

The Lateral Sacrococcygeal Ligament (*ligamentum sacrococcygeum laterale; inter-transverse ligament*).—The lateral sacrococcygeal ligament exists on either side and connects the transverse process of the coccyx to the lower lateral angle of the sacrum; it completes the foramen for the fifth sacral nerve.

A disk of **fibrocartilage** is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from those between the bodies of the vertebræ in that it is thinner, and its central part is firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally the coccyx is freely movable on the sacrum, most notably during pregnancy; in such cases a synovial membrane is present.

The **Interarticular Ligaments** are thin bands, which unite the cornua of the two bones.

The different segments of the coccyx are connected together by the extension downward of the anterior and posterior sacrococcygeal ligaments, thin annular disks of fibrocartilage being interposed between the segments. In the adult male, all the pieces become ossified together at a comparatively early period; but in the female, this does not commonly occur until a later period of life. At more advanced age the joint between the sacrum and coccyx is obliterated.

Movements.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are forward and backward; they are very limited. Their extent increases during pregnancy.

4. The Pubic Symphysis (*symphysis ossium pubis; articulation of the pubic bones*) (Fig. 444).—The articulation between the pubic bones is an amphiarthrodial joint, formed between the two oval articular surfaces of the bones. The ligaments of this articulation are:

The Anterior Pubic.	The Superior Pubic.
The Posterior Pubic.	The Arcuate Pubic.
The Interpubic Fibrocartilaginous Lamina.	

The Anterior Pubic Ligament (Fig. 442).—The anterior pubic ligament consists of several superimposed layers, which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeuroses of the *Obliqui externi* and the medial tendons of origin of the *Recti abdominis*. The deep fibres pass transversely across the symphysis, and are blended with the fibrocartilaginous lamina.

The Posterior Pubic Ligament.—The posterior pubic ligament consists of a few thin, scattered fibres, which unite the two pubic bones posteriorly.

The Superior Pubic Ligament (*ligamentum pubicum superius*).—The superior pubic ligament connects together the two pubic bones superiorly, extending laterally as far as the pubic tubercles.

*Interpubic
fibro-
cartilaginous
lamina*

FIG. 444.—Symphysis pubis exposed by a coronal section.

The Arcuate Pubic Ligament (*ligamentum arcuatum pubis; inferior pubic or subpubic ligament*).—The arcuate pubic ligament is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below, and forming the upper boundary of the pubic arch. *Above*, it is blended with the interpubic fibrocartilaginous lamina; *laterally*, it is attached to the inferior rami of the pubic bones; *below*, it is free, and is separated from the fascia of the urogenital diaphragm by an opening through which the deep dorsal vein of the penis passes into the pelvis.

The Interpubic Fibrocartilaginous Lamina (*lamina fibrocartilaginea interpubica; interpubic disk*).—The interpubic fibrocartilaginous lamina connects the opposed surfaces of the pubic bones. Each of these surfaces is covered by a thin layer of hyaline cartilage firmly joined to the bone by a series of nipple-like processes which accurately fit into corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate lamina of fibrocartilage which varies in thickness in different subjects. It often contains a cavity in its interior, probably formed by the softening and absorption of the fibrocartilage, since it rarely appears before the tenth year of life and is not lined

by synovial membrane. This cavity is larger in the female than in the male, but it is very doubtful whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint; it occasionally reaches to the front, and may extend the entire length of the cartilage. It may be easily demonstrated when present by making a coronal section of the symphysis pubis near its posterior surface (Fig. 444).

FIG. 445.—Coronal section of anterior sacral segment.

Mechanism of the Pelvis.—The pelvic girdle supports and protects the contained viscera and affords surfaces for the attachments of the trunk and lower limb muscles. Its most important mechanical function, however, is to transmit the weight of the trunk and upper limbs to the lower extremities.

It may be divided into two arches by a vertical plane passing through the acetabular cavities; the posterior of these arches is the one chiefly concerned in the function of transmitting the weight. Its essential parts are the upper three sacral vertebrae and two strong pillars of bone running from the sacroiliac articulations to the acetabular cavities. For the reception and diffusion of the weight each acetabular cavity is strengthened by two additional bars running toward

FIG. 446.—Coronal section of middle sacral segment.

the pubis and ischium. In order to lessen concussion in rapid changes of distribution of the weight, joints (sacroiliac articulations) are interposed between the sacrum and the iliac bones; an accessory joint (pubic symphysis) exists in the middle of the anterior arch. The sacrum forms the summit of the posterior arch; the weight transmitted falls on it at the lumbosacral articulation and, theoretically, has a component in each of two directions. One component of the force is expended in driving the sacrum downward and backward between the iliac bones, while the other thrusts the upper end of the sacrum downward and forward toward the pelvic cavity.

The movements of the sacrum are regulated by its form. Viewed as a whole, it presents the shape of a wedge with its base upward and forward. The first component of the force is therefore acting against the resistance of the wedge, and its tendency to separate the iliac bones is resisted by the sacroiliac and iliolumbar ligaments and by the ligaments of the pubic symphysis.

If a series of coronal sections of the sacroiliac joints be made, it will be found possible to divide

the articular portion of the sacrum into three segments: anterior, middle, and posterior. In the **anterior segment** (Fig. 445), which involves the first sacral vertebra, the articular surfaces show slight sinuities and are almost parallel to one another; the distance between their dorsal margins is, however, slightly greater than that between their ventral margins. This segment therefore presents a slight wedge shape with the truncated apex downward. The **middle segment** (Fig. 446) is a narrow band across the centres of the articulations. Its dorsal width is distinctly greater than its ventral, so that the segment is more definitely wedge-shaped, the truncated apex being again directed downward. Each articular surface presents in the centre a marked concavity from above downward, and into this a corresponding convexity of the iliac articular surface fits, forming an interlocking mechanism. In the **posterior segment** (Fig. 447) the ventral width is greater than the dorsal, so that the wedge form is the reverse of those of the other segments—i. e., the truncated apex is directed upward. The articular surfaces are only slightly concave.

FIG. 447.—Coronal section of posterior sacral segment.

Dislocation downward and forward of the sacrum by the second component of the force applied to it is prevented therefore by the middle segment, which interposes the resistance of its wedge shape and that of the interlocking mechanism on its surfaces; a rotatory movement, however, is produced by which the anterior segment is tilted downward and the posterior upward; the axis of this rotation passes through the dorsal part of the middle segment. The movement of the anterior segment is slightly limited by its wedge form, but chiefly by the posterior and interosseous sacroiliac ligaments; that of the posterior segment is checked to a slight extent by its wedge form, but the chief limiting factors are the sacrotuberous and sacrospinous ligaments. In all these movements the effect of the sacroiliac and ilio-lumbar ligaments and the ligaments of the symphysis pubis in resisting the separation of the iliac bones must be recognized.

During pregnancy the pelvic joints and ligaments are relaxed, and capable therefore of more extensive movements. When the fetus is being expelled the force is applied to the front of the sacrum. Upward dislocation is again prevented by the interlocking mechanism of the middle segment. As the fetal head passes the anterior segment the latter is carried upward, enlarging the antero-posterior diameter of the pelvic inlet; when the head reaches the posterior segment this also is pressed upward against the resistance of its wedge, the movement only being possible by the laxity of the joints and the stretching of the sacrotuberous and sacrospinous ligaments.

ARTICULATIONS OF THE UPPER EXTREMITY.

The articulations of the Upper Extremity may be arranged as follows:

- | | |
|----------------------------------|-------------------------|
| I. Sternoclavicular. | VI. Wrist. |
| II. Acromioclavicular. | VII. Intercarpal. |
| III. Shoulder. | VIII. Carpometacarpal. |
| IV. Elbow. | IX. Intermetacarpal. |
| V. Radioulnar. | X. Metacarpophalangeal. |
| XI. Articulations of the Digits. | |

1. Sternoclavicular Articulation (*Articulatio Sternoclavicularis*) (Fig. 448).

The sternoclavicular articulation is a double arthrodial joint. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the manubrium sterni, and the cartilage of the first rib. The articular surface of the clavicle is much larger than that of the sternum, and is invested with a layer of cartilage,¹ which is considerably thicker than that on the latter bone. The ligaments of this joint are:

- | | |
|---------------------------------|----------------------|
| The Articular Capsule. | The Interclavicular. |
| The Anterior Sternoclavicular. | The Costoclavicular. |
| The Posterior Sternoclavicular. | The Articular Disk. |

¹ According to Brush, the sternal end of the clavicle is covered by a tissue which is fibrous rather than cartilaginous in structure.

The Articular Capsule (*capsula articularis; capsular ligament*).—The articular capsule surrounds the articulation and varies in thickness and strength. In front and behind it is of considerable thickness, and forms the anterior and posterior sternoclavicular ligaments; but above, and especially below, it is thin and partakes more of the character of areolar than of true fibrous tissue.

The Anterior Sternoclavicular Ligament (*ligamentum sternoclaviculare anterior*).—The anterior sternoclavicular ligament is a broad band of fibres, covering the anterior surface of the articulation; it is attached *above* to the upper and front part of the sternal end of the clavicle, and, passing obliquely downward and medialward, is attached below to the front of the upper part of the manubrium sterni. This ligament is covered by the sternal portion of the Sternocleidomastoideus and the integument; *behind*, it is in relation with the capsule, the articular disk, and the two synovial membranes.

FIG. 448.—Sternoclavicular articulation. Anterior view.

The Posterior Sternoclavicular Ligament (*ligamentum sternoclaviculare posterius*).—The posterior sternoclavicular ligament is a similar band of fibres, covering the posterior surface of the articulation; it is attached *above* to the upper and back part of the sternal end of the clavicle, and, passing obliquely downward and medialward, is fixed below to the back of the upper part of the manubrium sterni. It is in relation, in *front*, with the articular disk and synovial membranes; *behind*, with the Sternohyoideus and Sternothyreideus.

The Interclavicular Ligament (*ligamentum interclaviculare*).—This ligament is a flattened band, which varies considerably in form and size in different individuals, it passes in a curved direction from the upper part of the sternal end of one clavicle to that of the other, and is also attached to the upper margin of the sternum. It is in relation, in *front*, with the integument and Sternocleidomastoidei; *behind*, with the Sternothyreidei.

The Costoclavicular Ligament (*ligamentum costoclaviculare; rhomboid ligament*).—This ligament is short, flat, strong, and rhomboid in form. Attached below to the upper and medial part of the cartilage of the first rib, it ascends obliquely backward and lateralward, and is fixed above to the costal tuberosity on the under surface of the clavicle. It is in relation, in *front*, with the tendon of origin of the Subclavius; *behind*, with the subclavian vein.

The Articular Disk (*discus articularis*).—The articular disk is flat and nearly circular, interposed between the articulating surfaces of the sternum and clavicle. It is attached, *above*, to the upper and posterior border of the articular surface of the clavicle; *below*, to the cartilage of the first rib, near its junction with the sternum; and by its circumference to the interclavicular and anterior and posterior sterno-

clavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre. It divides the joint into two cavities, each of which is furnished with a synovial membrane.

Synovial Membranes.—Of the two synovial membranes found in this articulation, the lateral is reflected from the sternal end of the clavicle, over the adjacent surface of the articular disk, and around the margin of the facet on the cartilage of the first rib; the medial is attached to the margin of the articular surface of the sternum and clothes the adjacent surface of the articular disk; the latter is the larger of the two.

Movements.—This articulation admits of a limited amount of motion in nearly every direction—upward, downward, backward, forward, as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of the shoulder girdle with the trunk. The movements attendant on elevation and depression of the shoulder take place between the clavicle and the articular disk, the bone rotating upon the ligament on an axis drawn from before backward through its own articular facet; when the shoulder is moved forward and backward, the clavicle, with the articular disk rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, around an axis drawn nearly vertically through the sternum; in the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves upon the articular disk and the latter, with the clavicle, rolls upon the sternum.¹ Elevation of the shoulder is limited principally by the costoclavicular ligament; depression, by the interclavicular ligament and articular disk. The muscles which raise the shoulder are the upper fibres of the Trapezius, the Levator scapulae, and the clavicular head of the Sternocleidomastoideus, assisted to a certain extent by the Rhomboidei, which pull the vertebral border of the scapula backward and upward and so raise the shoulder. The depression of the shoulder is principally effected by gravity assisted by the Subclavius, Pectoralis minor and lower fibres of the Trapezius. The shoulder is drawn backward by the Rhomboidei and the middle and lower fibres of the Trapezius, and forward by the Serratus anterior and Pectoralis minor.

Applied Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is owing to these, and to the fact that the force of the blow is usually transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint; it may be either forward, backward, or upward. Should it be displaced backward it may cause pressure on the trachea. The chief point worthy of note, as regards the construction of the joint, in connection with dislocation, is the fact that, owing to the shape of the articular surfaces, and the strength of the joint mainly depending upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

II. Acromioclavicular Articulation (*Articulatio Acromioclavicularis*; *Scapulo-clavicular Articulation*) (Fig. 449).

The acromioclavicular articulation is an arthrodial joint between the acromial end of the clavicle and the medial margin of the acromion of the scapula. Its ligaments are:

The Articular Capsule.	The Articular Disk.
The Superior Acromioclavicular.	The Coracoclavicular { Trapezoid and Conoid.
The Inferior Acromioclavicular.	

The Articular Capsule. (*capsula articularis*; *capsular ligament*).—The articular capsule completely surrounds the articular margins, and is strengthened above and below by the superior and inferior acromioclavicular ligaments.

The Superior Acromioclavicular Ligament (*ligamentum acromioclaviculare*).—This ligament is a quadrilateral band, covering the superior part of the articulation, and extending between the upper part of the acromial end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres, which interlace with the aponeuroses of the Trapezius and Deltoides; below, it is in contact with the articular disk when this is present.

¹ Humphry, On the Human Skeleton, page 402.

The Inferior Acromioclavicular Ligament.—This ligament is somewhat thinner than the preceding; it covers the under part of the articulation, and is attached to the adjoining surfaces of the two bones. It is in relation, *above*, in rare cases with the articular disk; *below*, with the tendon of the Supraspinatus.

The Articular Disk (*discus articularis*). The articular disk is frequently absent in this articulation. When present, it generally only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely, it completely divides the joint into two cavities.

The Synovial Membrane.—There is usually only one synovial membrane in this articulation, but when a complete articular disk is present, there are two.

FIG. 449.—The left shoulder and acromioclavicular joints, and the proper ligaments of the scapula.

The Coracoclavicular Ligament (*ligamentum coracoclaviculare*) (Fig. 449).—This ligament serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but is usually described with it, since it forms a most efficient means of retaining the clavicle in contact with the acromion. It consists of two fasciculi, called the **trapezoid** and **conoid ligaments**.

The Trapezoid Ligament (*ligamentum trapezoideum*), the anterior and lateral fasciculus, is broad, thin, and quadrilateral: it is placed obliquely between the coracoid process and the clavicle. It is attached, *below*, to the upper surface of the coracoid process; *above*, to the oblique ridge on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament, the two forming, by their junction, an angle projecting backward.

The Conoid Ligament (*ligamentum conoideum*), the posterior and medial fasciculus, is a dense band of fibres, conical in form, with its base directed upward. It is attached by its apex to a rough impression at the base of the coracoid process, medial to the trapezoid ligament; above, by its expanded base, to the coracoid

tuberosity on the under surface of the clavicle, and to a line proceeding medialward from it for 1.25 cm. These ligaments are in relation, in *front*, with the Subclavius and Deltoideus; *behind*, with the Trapezius.

Movements.—The movements of this articulation are of two kinds: (1) a gliding motion of the articular end of the clavicle on the acromion; (2) rotation of the scapula forward and backward upon the clavicle. The extent of this rotation is limited by the two portions of the coracoclavicular ligament, the trapezoid limiting rotation forward, and the conoid backward.

The acromioclavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Humphry, that if there had been no joint between the clavicle and scapula, the circular movement of the scapula on the ribs (as in throwing the shoulders backward or forward) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such positions, and it would have been impossible to give a blow straight forward with the full force of the arm; that is to say, with the combined force of the scapula, arm, and forearm. "This joint," as he happily says, "is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position, or nearly so." Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulder), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Applied Anatomy.—The acromioclavicular joint owes its security mainly to the coracoclavicular ligament, which limits the amount of movement of the acromial end of the clavicle either upward, backward, or forward. Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs upward; that is to say, the acromial end of the clavicle is displaced above the acromion of the scapula. The displacement is often incomplete, on account of the strong coracoclavicular ligaments, which remain untorn. The same difficulty exists, as in the sternoclavicular dislocation, in maintaining the ends of the bone in position after reduction.

THE LIGAMENTS OF THE SCAPULA.

The ligaments of the scapula (Fig. 449) are:

Coracoacromial, Superior-and Inferior Transverse.

The Coracoacromial Ligament (*ligamentum coracoacromiale*).—This ligament is a strong triangular band, extending between the coracoid process and the acromion. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle; and by its broad base to the whole length of the lateral border of the coracoid process. This ligament, together with the coracoid process and the acromion, forms a vault for the protection of the head of the humerus. It is in relation, *above*, with the clavicle and under surface of the Deltoideus; *below*, with the tendon of the Supraspinatus, a bursa being interposed. Its lateral border is continuous with a dense lamina that passes beneath the Deltoideus upon the tendons of the Supraspinatus and Infraspinatus. The ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and the base of the coracoid process, and joining together at the acromion. When the Pectoralis minor is inserted, as occasionally is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion of the ligament is then deficient.

The Superior Transverse Ligament (*ligamentum transversum scapulae superius*; *transverse* or *suprascapular ligament*).—This ligament converts the scapular notch into a foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the medial end of the scapular notch. The suprascapular nerve runs through the foramen; the transverse scapular vessels cross over the ligament. The ligament is sometimes ossified.

The Inferior Transverse Ligament (*ligamentum transversum scapulae inferius*; *spinoglenoid ligament*).—This ligament is a weak membranous band, situated

behind the neck of the scapula and stretching from the lateral border of the spine to the margin of the glenoid cavity. It forms an arch under which the transverse scapular vessels and suprascapular nerve enter the infraspinatous fossa.

III. Humeral Articulation or Shoulder-joint (*Articulatio Humeri*) (Fig. 449).

The shoulder-joint is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the hemispherical head of the humerus and the shallow glenoid cavity of the scapula, an arrangement which permits of very considerable movement, while the joint itself is protected against displacement by the tendons which surround it. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use, therefore, is to limit

FIG. 450.—Capsule of shoulder-joint (distended). Anterior aspect.

the amount of movement. The joint is protected above by an arch, formed by the coracoid process, the acromion, and the coracoacromial ligament. The articular cartilage on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case with the articular cartilage of the glenoid cavity. The ligaments of the shoulder are:

The Articular Capsule.
The Coracohumeral.

The Glenohumeral.
The Transverse Humeral.

The Glenoidal Labrum.¹

The Articular Capsule (*capsula articularis*; *capsular ligament*) (Fig. 450).—The articular capsule completely encircles the joint, being attached, above, to the circumference of the glenoid cavity beyond the glenoidal labrum; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere,

¹ The long tendon of origin of the biceps brachii also acts as one of the ligaments of this joint. See the observations on page 383, on the function of the muscles passing over more than one joint.

and is so remarkably loose and lax, that it has no action in keeping the bones in contact, but allows them to be separated from each other more than 2.5 cm., an evident provision for that extreme freedom of movement which is peculiar to this articulation. It is strengthened, *above*, by the Supraspinatus; *below*, by the long head of the Triceps brachii; *behind*, by the tendons of the Infraspinatus and Teres minor; and in *front*, by the tendon of the Subscapularis. There are usually three openings in the capsule. One anteriorly, below the coracoid process, establishes a communication between the joint and a bursa beneath the tendon of the Subscapularis. The second, which is not constant, is at the posterior part, where an opening sometimes exists between the joint and a bursal sac under the tendon of the Infraspinatus. The third is between the tubercles of the humerus, for the passage of the long tendon of the Biceps brachii.

The Coracohumeral Ligament (*ligamentum coracohumerale*).—This ligament is a broad band which strengthens the upper part of the capsule. It arises from the lateral border of the coracoid process, and passes obliquely downward and lateralward to the front of the greater tubercle of the humerus, blending with the tendon of the Supraspinatus. This ligament is intimately united to the capsule by its hinder and lower border; but its anterior and upper border presents a free edge, which overlaps the capsule.

Glenohumeral Ligaments.—In addition to the coracohumeral ligament, three supplemental bands, which are named the **glenohumeral ligaments**, strengthen the capsule. These may be best seen by opening the capsule at the back of the joint and removing the head of the humerus. One on the medial side of the joint passes from the medial edge of the glenoid cavity to the lower part of the lesser tubercle of the humerus. A second at the lower part of the joint extends from the under edge of the glenoid cavity to the under part of the anatomical neck of the humerus. A third at the upper part of the joint is fixed above to the apex of the glenoid cavity close to the root of the coracoid process, and passing downward along the medial edge of the tendon of the Biceps brachii, is attached below to a small depression above the lesser tubercle of the humerus. In addition to these, the capsule is strengthened in front by two bands derived from the tendons of the Pectoralis major and Teres major respectively.

The Transverse Humeral Ligament (Fig. 450) is a broad band passing from the lesser to the greater tubercle of the humerus, and always limited to that portion of the bone which lies above the epiphysial line. It converts the intertubercular groove into a canal, and is the homologue of the strong process of bone which connects the summits of the two tubercles in the musk ox.

The Glenoidal Labrum (*labrium glenoidale; glenoid ligament*) is a fibrocartilaginous rim attached around the margin of the glenoid cavity. It is triangular on section, the base being fixed to the circumference of the cavity, while the free edge is thin and sharp. It is continuous above with the tendon of the long head of the Biceps brachii, which gives off two fasciculi to blend with the fibrous tissue of the labrum. It deepens the articular cavity, and protects the edges of the bone.

Synovial Membrane.—The synovial membrane is reflected from the margin of the glenoid cavity over the labrum; it is then reflected over the inner surface of the capsule, and covers the lower part and sides of the anatomical neck of the humerus as far as the articular cartilage on the head of the bone. The tendon of the long head of the Biceps brachii passes through the capsule and is enclosed in a tubular sheath of synovial membrane, which is reflected upon it from the summit of the glenoid cavity and is continued around the tendon into the intertubercular groove as far as the surgical neck of the humerus (Fig. 450). The tendon thus traverses the articulation, but it is not contained within the synovial cavity.

Bursæ.—The bursæ in the neighborhood of the shoulder-joint are the following: (1) A constant bursa is situated between the tendon of the Subscapularis muscle and the capsule; it communicates with the synovial cavity through an opening in the front of the capsule; (2) a bursa which occasionally communicates with the joint is sometimes found between the tendon of the Infraspinatus and the capsule; (3) a large bursa exists between the under surface of the Deltoideus

and the capsule, but does not communicate with the joint; this bursa is prolonged under the acromion and coracoacromial ligament, and intervenes between these structures and the capsule; (4) a large bursa is situated on the summit of the acromion; (5) a bursa is frequently found between the coracoid process and the capsule; (6) a bursa exists beneath the Coracobrachialis; (7) one lies between the Teres major and the long head of the Triceps brachii; (8) one is placed in front of, and another behind, the tendon of the Latissimus dorsi.

The **muscles** in relation with the joint are, *above*, the Supraspinatus; *below*, the long head of the Triceps brachii; *in front*, the Subscapularis; *behind*, the Infraspinatus and Teres minor; *within*, the tendon of the long head of the Biceps brachii. The Deltoideus covers the articulation in front, behind, and laterally.

The **arteries** supplying the joint are articular branches of the anterior and posterior humeral circumflex, and transverse scapular.

The **nerves** are derived from the axillary and suprascapular.

Movements.—The shoulder-joint is capable of every variety of movement, flexion, extension, abduction, adduction, circumduction, and rotation. The humerus is *flexed* (drawn forward) by the Pectoralis major, anterior fibres of the Deltoideus, Coracobrachialis, and when the forearm is flexed, by the Biceps brachii; *extended* (drawn backward) by the Latissimus dorsi, Teres major, posterior fibres of the Deltoideus, and, when the forearm is extended, by the Triceps brachii; it is *abducted* by the Deltoideus and Supraspinatus; it is *adducted* by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major, and by the weight of the limb; it is *rotated outward* by the Infraspinatus and Teres minor; and it is *rotated inward* by the Subscapularis, Latissimus dorsi, Teres major, Pectoralis major, and the anterior fibres of the Deltoideus.

The most striking peculiarities in this joint are: (1) The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when this latter is supplemented by the glenoidal labrum. (2) The looseness of the capsule of the joint. (3) The intimate connection of the capsule with the muscles attached to the head of the humerus. (4) The peculiar relation of the tendon of the long head of the Biceps brachii to the joint.

It is in consequence of the relative sizes of the two articular surfaces, and the looseness of the articular capsule, that the joint enjoys such free movement in all directions. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces, and by the tension of the fibres of the capsule, together with that of the muscles acting as accessory ligaments, the arm can be carried considerably farther by the movements of the scapula, involving, of course, motion at the acromio- and sternoclavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint (see pages 411 and 413). The extent of the scapular movements is very considerable, especially in extreme elevation of the arm, a movement best accomplished when the arm is thrown somewhat forward and outward, because the margin of the head of the humerus is by no means a true circle; its greatest diameter is from the intertubercular groove, downward, medialward, and backward, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of this measurement. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoid process and the coracoacromial ligament, constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about 2.5 cm. from the scapula when the muscles are dissected from the capsule, and an opening made in it to counteract the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere, an arrangement which "renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest" (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch, enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that "abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity; adduction by the tension of the coracohumeral ligament" (Beaunis et Bouchard). Cleland¹ maintains that the limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoidal labrum fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

The scapula is capable of being moved upward and downward, forward and backward, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator scapulae, and the Rhomboidei; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn *backward* by the Rhomboidei and the middle and lower fibres of the Trapezius, and *forward* by the Serratus anterior and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very

¹ Journal of Anatomy and Physiology, 1867, i, 85.

considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side, the *Deltoides* and *Supraspinatus* can only lift it to a right angle with the trunk, the further elevation of the limb being effected by the *Trapezius* and *Serratus anterior* moving the scapula on the wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of this bone compensating to a very great extent for the immobility of the joint.

Cathcart¹ has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only while passing from the hanging to the horizontal position, but also in travelling upward as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—i. e., the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The intimate union of the tendons of the *Supraspinatus*, *Infraspinatus*, *Teres minor* and *Subscapularis* with the capsule, converts these muscles into elastic and spontaneously acting ligaments of the joint.

The peculiar relations of the tendon of the long head of the *Biceps brachii* to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously discussed (see page 383). It strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion, when the *Deltoides* contracts; it thus fixes the head of the humerus as the centre of motion in the glenoid cavity. By its passage along the intertubercular groove it assists in steadying the head of the humerus in the various movements of the arm. When the arm is raised from the side it assists the *Supraspinatus* and *Infraspinatus* in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the *Latissimus dorsi* and *Pectoralis major*, as in climbing and many other movements.

Applied Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, between the tendons of the *Subscapularis* and the *Triceps brachii*, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front of and behind the joint. As the muscles at the back are stronger than those in front, and especially since the long head of the *Triceps brachii* prevents the bone from passing backward, dislocation forward is much the more common. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid. Occasionally, in consequence of a greater amount of force being brought to bear on the limb, the head is driven farther medialward, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backward and remains in the *infraspinatus* fossa, beneath the spine (subspinous).

The shoulder-joint may be the seat of any of those inflammatory affections, either acute or chronic, which attack joints, though perhaps less frequently than some other articulations of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyemia, or may follow secondarily on acute epiphysitis in infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended, and the contour of the joint rounded. Special projections may occur at the sites of the openings in the capsule. Thus a swelling may appear just medial to the lesser tubercle, from effusion into the bursa beneath the *Subscapularis*; or, again, a swelling which is sometimes bilobed may be seen in the interval between the *Deltoides* and *Pectoralis major*, from effusion into the diverticulum which runs down the intertubercular groove with the tendon of the *Biceps brachii*. The effusion into the joint cavity can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt. In cases of septic synovitis, where incision is required, the opening should be made in front, over the most prominent point of the swelling. After the pus has been evacuated a counter-opening should be made behind, so as to ensure efficient drainage.

Tuberculous arthritis not infrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result, or long-protracted suppuration may necessitate

¹ *Journal of Anatomy and Physiology*, 1884, vol. xviii.

excision. This joint is also one of those which is most liable to be the seat of osteoarthritis, and may also be affected in gout and rheumatism; or in locomotor ataxia, when it becomes the seat of Charcot's disease.

Ankylosis is occasionally met with in the shoulder-joint as the result of destructive changes. The ankylosis usually takes place with the arm in a dependent position, and any attempt to raise the arm is attended by a rotation of the scapula on the wall of the chest.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain. The operation is best performed by making an incision from the middle of the coracoacromial ligament down the arm for about 7 or 8 cm.; this will expose the intertubercular groove containing the tendon of the Biceps brachii, which should be hooked out of the way. The capsule is freely opened, and the muscles attached to the greater and lesser tubercles of the humerus are stripped off with the capsule, without dividing their attachments to the latter. The head of the bone can then be thrust out of the wound and sawn off; or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible.

IV. Elbow-joint (*Articulatio Cubiti*) (Figs. 451, 452).

The elbow-joint is a ginglymus or hinge-joint. The trochlea of the humerus is received into the semilunar notch of the ulna, and the capitulum of the humerus articulates with the fovea on the head of the radius. The articular surfaces are connected together by a **capsule**, which is thickened medially and laterally, and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:

The Anterior.
The Posterior.

The Ulnar Collateral.
The Radial Collateral.

The Anterior Ligament (Fig. 451).—The anterior ligament is a broad and thin fibrous layer covering the anterior surface of the joint. It is attached to the *front* of the medial epicondyle and to the front of the humerus immediately above the coronoid and radial fossæ; *below*, to the anterior surface of the coronoid process of the ulna and to the annular ligament (page 422), being continuous on either side with the collateral ligaments. Its superficial fibres pass obliquely from the medial epicondyle of the humerus to the annular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but are inserted mainly into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in *front*, with the Brachialis, except at its most lateral part.

The Posterior Ligament (Fig. 452).—This posterior ligament is thin and membranous, and consists of transverse and oblique fibres. *Above*, it is attached to the humerus immediately behind the capitulum and close to the medial margin of the trochlea, to the margins of the olecranon fossa, and to the back of the lateral epicondyle some little distance from the trochlea. *Below*, it is fixed to the upper and lateral margins of the olecranon, to the posterior part of the annular ligament, and to the ulna behind the radial notch. The transverse fibres form a strong band which bridges across the olecranon fossa; under cover of this band a pouch of synovial membrane and a pad of fat project into the upper part of the fossa when the joint is extended. In the fat are a few scattered fibrous bundles, which pass from the deep surface of the transverse band to the upper part of the fossa. This ligament is in relation, *behind*, with the tendon of the Triceps brachii and the Anconeus.

The Ulnar Collateral Ligament (*ligamentum collaterale ulnare; internal lateral ligament*) (Fig. 451).—This ligament is a thick triangular band consisting of two

portions, an anterior and posterior united by a thinner intermediate portion. The **anterior portion**, directed obliquely forward, is attached, *above*, by its apex, to the front part of the medial epicondyle of the humerus; and, *below*, by its broad base to the medial margin of the coronoid process. The **posterior portion**, also of triangular form, is attached, *above*, by its apex, to the lower and back part of the medial epicondyle; *below*, to the medial margin of the olecranon. Between these two bands a few intermediate fibres descend from the medial epicondyle to blend with a *transverse band* which bridges across the notch between the olecranon and the coronoid process. This ligament is in relation with the Triceps brachii and Flexor carpi ulnaris and the ulnar nerve, and gives origin to part of the Flexor digitorum sublimis.

FIG. 451.—Left elbow-joint, showing anterior and ulnar collateral ligaments.

FIG. 452.—Left elbow-joint, showing posterior and radial collateral ligaments.

The Radial Collateral Ligament (*ligamentum collaterale radiale*; *external lateral ligament*) (Fig. 452).—This ligament is a short and narrow fibrous band, less distinct than the ulnar collateral, attached, *above*, to a depression below the lateral epicondyle of the humerus; *below*, to the annular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the lateral margin of the ulna. It is intimately blended with the tendon of origin of the Supinator.

Synovial Membrane (Figs. 453, 454).—The synovial membrane is very extensive. It extends from the margin of the articular surface of the humerus, and lines the coronoid, radial and olecranon fossæ on that bone; it is reflected over the deep surface of the capsule and forms a pouch between the radial notch, the deep surface of the annular ligament, and the circumference of the head of the radius. Projecting between the radius and ulna into the cavity is a crescentic fold of

synovial membrane, suggesting the division of the joint into two; one the humeroradial, the other the humeroulnar.

Between the capsule and the synovial membrane are three masses of fat: the largest, over the olecranon fossa, is pressed into the fossa by the Triceps brachii during the flexion; the second, over the coronoid fossa, and the third, over the radial fossa, are pressed by the Brachialis into their respective fossae during extension.

The **muscles** in relation with the joint are, in *front*, the Brachialis; *behind*, the Triceps brachii and Anconæus; *laterally*, the Supinator, and the common tendon of origin of the Extensor muscles; *medially*, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris.

The **arteries** supplying the joint are derived from the anastomosis between the profunda and the superior and inferior ulnar collateral branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar, and the recurrent branch of the radial. These vessels form a complete anastomotic network around the joint.

FIG. 453.—Capsule of elbow-joint (distended).
Anterior aspect.

FIG. 454.—Capsule of elbow-joint (distended)
Posterior aspect.

The **nerves** of the joint are a twig from the ulnar, as it passes between the medial condyle and the olecranon; a filament from the musculocutaneous, and two from the median.

Movements.—The elbow-joint comprises three different portions—*vis.*, the joint between the ulna and humerus, that between the head of the radius and the humerus, and the proximal radioulnar articulation, described below. All these articular surfaces are enveloped by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlea of the humerus, this movement does not take place in the antero-posterior plane of the body of the humerus.

When the forearm is extended and supinated, the axes of the arm and forearm are not in the same line; the arm forms an obtuse angle with the forearm, the hand and forearm being directed lateralward. During flexion, however, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The accurate adaptation of the trochlea of the humerus, with its prominences and depressions, to the semilunar notch of the ulna, prevents any lateral movement. *Flexion* is produced by the action of the Biceps brachii and Brachialis, assisted by the Brachioradialis and the muscles arising from the medial condyle of the humerus; *extension*, by the Triceps brachii and Anconaeus, assisted by the Extensors of the wrist, the Extensor digitorum communis, and the Extensor digiti quinti proprius.

The joint between the head of the radius and the capitulum of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis and allow of movement in all directions, were it not for the annular ligament, by which the head of the radius is bound to the radial notch of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise tend to occur, from the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament, the tendon of the Biceps brachii would be liable to pull the head of the radius out of the joint. The head of the radius is not in complete contact with the capitulum of the humerus in all positions of the joint. The capitulum occupies only the anterior and inferior surfaces of the lower end of the humerus, so that in complete extension a part of the radial head can be plainly felt projecting at the back of the articulation. In full flexion the movement of the radial head is hampered by the compression of the surrounding soft parts, so that the freest rotatory movement of the radius on the humerus (pronation and supination) takes place in semiflexion, in which position the two articular surfaces are in most intimate contact. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint; the limitation of flexion is also aided by the soft structures of the arm and forearm coming into contact.

In any position of flexion or extension, the radius, carrying the hand with it, can be rotated in the proximal radioulnar joint. The hand is directly articulated to the lower surface of the radius only, and the ulnar notch on the lower end of the radius travels around the lower end of the ulna. The latter bone is excluded from the wrist-joint by the articular disk. Thus, rotation of the head of the radius around an axis passing through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Applied Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong collateral ligaments and the support which the joint derives from the mass of muscles attached to each epicondyle of the humerus, lateral displacement of the bones is very uncommon; whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, occurs much more frequently. Dislocation backward takes place when the forearm is in a position of extension, and forward when in a position of flexion. For, in the extended position, the coronoid process is not locked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon is in the olecranon fossa, and entirely prevents displacement forward. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backward, while the olecranon, having left the olecranon fossa, is not so efficient in preventing a forward displacement. When lateral dislocation does take place it is generally incomplete. Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation. As a rule, in young persons, the application of any severe violence to a joint is more likely to produce a fracture of bone than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The joint-cavity then becomes distended with fluid, the bulging showing itself principally around the olecranon, in consequence of the laxness of the posterior ligament. Again, there is often some swelling just above the head of the radius, in the line of the radiohumeral joint, or the whole elbow may assume a fusiform appearance. There is not generally much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps brachii; occasionally the pus discharges itself in front, near the insertion of the Brachialis. In cases of suppurative synovitis, incisions should be made into the joint on either side of the olecranon, care being taken to avoid wounding the ulnar nerve on the medial side. Chronic synovitis, usually of tuberculous origin, is of common occurrence in the elbow-joint; in such cases the forearm tends to assume the position of semiflexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind that if ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. The elbow-joint is also sometimes affected with osteoarthritis, but less commonly than some of the larger joints.

Excision of the elbow is principally required for one of three conditions—viz., tuberculous arthritis, injury and its results, or faulty ankylosis—but may be necessary for some other rarer

conditions, such as disorganizing arthritis after pyemia and unreduced dislocations. The results of the operation are, as a rule, more favorable than those of excision of any other joint, especially in any of the first three conditions mentioned above. The operation is best performed by a vertical incision down the back of the joint; a straight incision is made about 10 cm. long, the mid-point of which is on a level with and a little to the medial side of the tip of the olecranon. This incision is made down to the bone, through the substance of the *Triceps brachii*. The operator, guarding the soft parts with his thumb-nail, separates them from the bone with the point of his knife. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which as it courses down between the medial epicondyle and the olecranon lies parallel but a little medial to his incision; and the prolongation of the *Triceps brachii* into the deep fascia of the forearm over the *Anconaeus*. Having cleared the bones and divided the collateral and posterior ligaments, the forearm is strongly flexed and the ends of the bones turned out and sawn off. The turning out of the ends of the bones is rendered easier by first cutting off the olecranon with a pair of cutting bone forceps. The section of the humerus should be through the base of the epicondyles, that of the ulna and radius should be just below the level of the radial notch of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive movements must be commenced early—that is to say, about the tenth day. It is most important to maintain the continuity of the *Triceps brachii* with the deep fascia of the forearm, so as to obtain good power of extension in the new joint.

V. Radioulnar Articulations (*Articulatio Radioulnaris*).

The articulation of the radius with the ulna is effected by ligaments which connect together the extremities as well as the bodies of these bones. The ligaments may, consequently, be subdivided into three sets: 1, those of the proximal radioulnar articulation; 2, the middle radioulnar ligaments; 3, those of the distal radioulnar articulation.

Proximal Radioulnar Articulation (*articulatio radioulnaris proximalis; superior radioulnar joint*).—This articulation is a trochoid or pivot-joint between the circumference of the head of the radius and the ring formed by the radial notch of the ulna and the *annular ligament*.

<i>Head of radius</i> (cut)	<i>Quadrato</i> <i>ligament</i>	<i>Semilunar</i> <i>notch</i>
--------------------------------	------------------------------------	----------------------------------

Olecranon (cut)

FIG. 455.—Annular ligament of radius, from above. The head of the radius has been sawn off and the bone dislodged from the ligament.

The Annular Ligament (*ligamentum annulare radii; orbicular ligament*) (Fig. 455).—This ligament is a strong band of fibres, which encircles the head of the radius, and retains it in contact with the radial notch of the ulna. It forms about four-fifths of the osseo-fibrous ring, and is attached to the anterior and posterior margins of the radial notch; a few of its lower fibres are continued around below the cavity and form at this level a complete fibrous ring. Its upper border blends with the anterior and posterior ligaments of the elbow, while from its lower border a thin

loose membrane passes to be attached to the neck of the radius; a thickened band which extends from the inferior border of the annular ligament below the radial notch to the neck of the radius is known as the **quadrate ligament**. The **superficial surface** of the annular ligament is strengthened by the radial collateral ligament of the elbow, and affords origin to part of the Supinator. Its **deep surface** is smooth, and lined by synovial membrane, which is continuous with that of the elbow-joint.

Movements.—The movements allowed in this articulation are limited to rotatory movements of the head of the radius within the ring formed by the annular ligament and the radial notch of the ulna; rotation forward being called *pronation*; rotation backward, *supination*. Supination is performed by the Biceps brachii and Supinator, assisted to a slight extent by the Extensor muscles of the thumb. Pronation is performed by the Pronator teres and Pronator quadratus.

Applied Anatomy.—Dislocation of the head of the radius alone is a not uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the annular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downward in the annular ligament, the upper border of which becomes folded over the head of the radius, between it and the capitulum of the humerus. The forearm becomes fixed in a position of semiflexion, midway between supination and pronation, and great pain is complained of upon any attempt to move the joint. The synovial membrane of the proximal radioulnar joint is directly continuous with that of the elbow-joint, and, therefore, any septic or tuberculous disease which affects the latter also involves the former joint. The proximal radioulnar joint is always removed in an excision of the elbow (see p. 422).

Middle Radioulnar Union.—The shafts of the radius and ulna are connected by the Oblique Cord and the Interosseous Membrane.

The Oblique Cord (*chorda obliqua; oblique ligament*) (Fig. 451).—The oblique cord is a small, flattened band, extending downward and lateralward, from the lateral side of the tubercle of the ulna at the base of the coronoid process to the radius a little below the radial tuberosity. Its fibres run in the opposite direction to those of the interosseous membrane. It is sometimes wanting.

The Interosseous Membrane (*membrana interossea antebrachii*).—The interosseous membrane is a broad and thin plane of fibrous tissue descending obliquely downward and medialward, from the interosseous crest of the radius to that of the ulna; the lower part of the membrane is attached to the posterior of the two lines into which the interosseous crest of the radius divides. It is deficient above, commencing about 2.5 cm. beneath the tuberosity of the radius; is broader in the middle than at either end; and presents an oval aperture a little above its lower margin for the passage of the volar interosseous vessels to the back of the forearm. This membrane serves to connect the bones, and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique cord is a gap, through which the dorsal interosseous vessels pass. Two or three fibrous bands are occasionally found on the dorsal surface of this membrane; they descend obliquely from the ulna toward the radius, and have consequently a direction contrary to that of the other fibres. The membrane is in relation, in *front*, by its upper three-fourths, with the Flexor pollicis longus on the radial side, and with the Flexor digitorum profundus on the ulnar, lying in the interval between which are the volar interosseous vessels and nerve; by its lower fourth with the Pronator quadratus; *behind*, with the Supinator, Abductor pollicis longus, Extensor pollicis brevis, Extensor pollicis longus, Extensor indicis proprius; and, near the wrist, with the volar interosseous artery and dorsal interosseous nerve.

Distal Radioulnar Articulation (*articulatio radioulnaris distalis; inferior radioulnar joint*).—This is a pivot-joint formed between the head of the ulna and the ulnar notch on the lower end of the radius. The articular surfaces are connected together by the following ligaments:

The Volar Radioulnar.

The Dorsal Radioulnar.

The Articular Disk.

The Volar Radioulnar Ligament (*anterior radioulnar ligament*) (Fig. 456).—This ligament is a narrow band of fibres extending from the anterior margin of the ulnar notch of the radius to the front of the head of the ulna.

The Dorsal Radioulnar Ligament (*posterior radioulnar ligament*) (Fig. 457).—This ligament extends between corresponding surfaces on the dorsal aspect of the articulation.

Distal radio-
articulation
Wrist.

Intercarpal articula

Carpometacarpal
articulations

FIG. 457.—Ligaments of wrist. Posterior view.

The Articular Disk (*discus articularis; triangular fibrocartilage*) (Fig. 458).—The articular disk is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower ends of the ulna and radius firmly together. Its

periphery is thicker than its centre, which is occasionally perforated. It is attached by its apex to a depression between the styloid process and the head of the ulna; and by its base, which is thin, to the prominent edge of the radius, which separates the ulnar notch from the carpal articular surface. Its margins are united to the ligaments of the wrist-joint. Its **upper surface**, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its **under surface**, also concave and smooth, forms part of the wrist-joint and articulates with the triangular bone and medial part of the lunate. Both surfaces are clothed by synovial membrane; the upper, by that of the distal radioulnar articulation, the under, by that of the wrist.

FIG. 458.—Vertical section through the articulations at the wrist, showing the synovial cavities.

Synovial Membrane (Fig. 458).—The synovial membrane of this articulation is extremely loose, and extends upward as a recess (*recessus sacciformis*) between the radius and the ulna.

Movements.—The movements in the distal radioulnar articulation consist of rotation of the lower end of the radius around an axis which passes through the centre of the head of the ulna. When the radius rotates forward, *pronation* of the forearm and hand is the result; and when backward, *supination*. It will thus be seen that in pronation and supination the radius describes the segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement the head of the ulna is not stationary, but describes a curve in a direction opposite to that taken by the head of the radius. This, however, is not to be regarded as a rotation of the ulna—the curve which the head of this bone describes is due to a combined antero-posterior and rotatory movement, the former taking place almost entirely at the elbow-joint, the latter at the shoulder-joint.

VI. Radiocarpal Articulation or Wrist-joint (*Articulatio Radiocarpeæ*) (Figs. 456, 457).

The wrist-joint is a condyloid articulation. The parts forming it are the lower end of the radius and under surface of the articular disk above; and the navicular, lunate, and triangular bones below. The articular surface of the radius and the under surface of the articular disk form together a transversely elliptical concave surface, the **receiving cavity**. The superior articular surfaces of the navicular, lunate, and triangular form a smooth convex surface, the **condyle**, which is received

into the concavity. The joint is surrounded by a capsule, strengthened by the following ligaments:

The Volar Radiocarpal.

The Ulnar Collateral.

The Dorsal Radiocarpal.

The Radial Collateral.

The Volar Radiocarpal Ligament (*ligamentum radiocarpeum volare; anterior ligament*) (Fig. 456).—This ligament is a broad membranous band, attached above to the anterior margin of the lower end of the radius, to its styloid process, and to the front of the lower end of the ulna; its fibres pass downward and medialward to be inserted into the volar surfaces of the navicular, lunate, and triangular bones, some being continued to the capitate. In addition to this broad membrane, there is rounded fasciculus, superficial to the rest, which reaches from the base of the styloid process of the ulna to the lunate and triangular bones. The ligament is perforated by apertures for the passage of vessels, and is in relation, in *front*, with the tendons of the Flexor digitorum profundus and Flexor pollicis longus; *behind*, it is closely adherent to the anterior border of the articular disk of the distal radioulnar articulation.

The Dorsal Radiocarpal Ligament (*ligamentum radiocarpeum dorsale; posterior ligament*) (Fig. 457).—The dorsal radiocarpal ligament less thick and strong than the volar, is attached, *above*, to the posterior border of the lower end of the radius; its fibres are directed obliquely downward and medialward, and are fixed, *below*, to the dorsal surfaces of the navicular, lunate, and triangular, being continuous with those of the dorsal intercarpal ligaments. It is in relation, *behind*, with the Extensor tendons of the fingers; in *front*, it is blended with the articular disk.

The Ulnar Collateral Ligament (*ligamentum collaterale carpi ulnare; internal lateral ligament*) (Fig. 456).—The ulnar collateral ligament is a rounded cord, attached above to the end of the styloid process of the ulna, and dividing below into two fasciculi, one of which is attached to the medial side of the triangular bone, the other to the pisiform and transverse carpal ligament.

The Radial Collateral Ligament (*ligamentum collaterale carpi radiale; external lateral ligament*) (Fig. 456).—The radial collateral ligament extends from the tip of the styloid process of the radius to the radial side of the navicular, some of its fibres being prolonged to the greater multangular bone and the transverse carpal ligament. It is in relation with the radial artery, which separates the ligament from the tendons of the Abductor pollicis longus and Extensor pollicis brevis.

Synovial Membrane (Fig. 458).—The synovial membrane lines the deep surfaces of the ligaments above described, extending from the margin of the lower end of the radius and articular disk above to the margins of the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

The wrist-joint is covered in front by the Flexor, and behind by the Extensor tendons.

The **arteries** supplying the joint are the volar and dorsal carpal branches of the radial and ulnar, the volar and dorsal metacarpals, and some ascending branches from the deep volar arch.

The **nerves** are derived from the ulnar and dorsal interosseous.

Movements.—The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. They will be studied with those of the carpus, with which they are combined.

Applied Anatomy.—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movements which take place between the several bones serve to break the jars that result from falls or blows on the hand. Dislocation backward, which is the more common, simulates to a considerable extent Colles' fracture of the radius, and is liable to be mistaken for it. The differential diagnosis can be easily made by observing the relative positions of the styloid processes of the radius and the ulna. In the natural condition the styloid process of the radius is on a lower level, *i. e.*, nearer the ground, when the arm hangs by the side than that of the ulna, and this relationship is not disturbed in dislocation. In Colles' fracture the styloid process of the radius is on the same level as, or even a higher level than, that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis. When the joint cavity is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighborhood. Chronic inflammation of the wrist is generally tuberculous, and often leads to similar disease in the mucous sheaths of adjacent tendons and the intercarpal joints, with resulting ankylosis.

VII. Intercarpal Articulations (*Articulationes Intercarpeae*; Articulations of the Carpus).

These articulations may be subdivided into three sets:

1. The Articulations of the Proximal Row of Carpal Bones.
2. The Articulations of the Distal Row of Carpal Bones.
3. The Articulations of the Two Rows with each Other.

Articulations of the Proximal Row of Carpal Bones.—These are arthrodial joints. The navicular, lunate, and triangular are connected by dorsal, volar, and interosseous ligaments.

The Dorsal Ligaments (*ligamenta intercarpea dorsalia*).—The dorsal ligaments, two in number, are placed transversely behind the bones of the first row; they connect the navicular and lunate, and the lunate and triangular.

The Volar ligaments (*ligamenta intercarpea volaria*; *palmar ligaments*).—The volar ligaments, also two, connect the navicular and lunate, and the lunate and triangular; they are less strong than the dorsal, and placed very deeply behind the Flexor tendons and the volar radiocarpal ligament.

The Interosseous Ligaments (*ligamenta intercarpea interossea*) (Fig. 458).—The interosseous ligaments are two narrow bundles, one connecting the lunate with the navicular, the other joining it to the triangular. They are on a level with the superior surfaces of these bones, and their upper surfaces are smooth, and form part of the convex articular surface of the wrist-joint.

The ligaments connecting the pisiform bone are the articular capsule and the two volar ligaments.

The **articular capsule** is a thin membrane which connects the pisiform to the triangular; it is lined by synovial membrane.

The two **volar ligaments** are strong fibrous bands; one, the **pisohamate ligament**, connects the pisiform to the hamate, the other, the **pisometacarpal ligament**, joins the pisiform to the base of the fifth metacarpal bone (Fig. 456). These ligaments are, in reality, prolongations of the tendon of the Flexor carpi ulnaris.

Articulations of the Distal Row of Carpal Bones.—These also are arthrodial joints; the bones are connected by dorsal, volar, and interosseous ligaments.

The Dorsal Ligaments (*ligamenta intercarpea dorsalia*).—The dorsal ligaments, three in number, extend transversely from one bone to another on the dorsal surface, connecting the greater with the lesser multangular, the lesser multangular with the capitate, and the capitate with the hamate.

The Volar Ligaments (*ligamenta intercarpea volaria*; *palmar ligaments*).—The volar ligaments, also three, have a similar arrangement on the volar surface.

The Interosseous Ligaments (*ligamenta intercarpea interossea*).—The three interosseous ligaments are much thicker than those of the first row; one is placed between the capitate and the hamate, a second between the capitate and the lesser multangular, and a third between the greater and lesser multangulars. The first is much the strongest, and the third is sometimes wanting.

Articulations of the Two Rows of Carpal Bones with Each Other.—The joint between the navicular, lunate, and triangular on the one hand, and the second row of carpal bones on the other, is named the **midcarpal joint**, and is made up of three distinct portions: in the centre the head of the capitate and the superior

surface of the hamate articulate with the deep cup-shaped cavity formed by the navicular and lunate, and constitute a sort of ball-and-socket joint. On the radial side the greater and lesser multangulares articulate with the navicular, and on the ulnar side the hamate articulates with the triangular, forming gliding joints.

The ligaments are: volar, dorsal, ulnar and radial collateral.

The Volar Ligaments (*ligamenta intercarpea volaria; anterior or palmar ligaments*).

—The volar ligaments consist of short fibres, which pass, for the most part, from the volar surfaces of the bones of the first row to the front of the capitate.

The Dorsal Ligaments (*ligamenta intercarpea dorsalia; posterior ligaments*).

—The dorsal ligaments consist of short, irregular bundles passing between the dorsal surfaces of the bones of the first and second rows.

The Collateral Ligaments (*lateral ligaments*).—The collateral ligaments are very short; one is placed on the radial, the other on the ulnar side of the carpus; the former, the stronger and more distinct, connects the navicular and greater multangular, the latter the triangular and hamate; they are continuous with the collateral ligaments of the wrist-joint. In addition to these ligaments, a slender interosseous band sometimes connects the capitate and the navicular.

Synovial Membrane.—The synovial membrane of the carpus is very extensive (Fig. 458), and bounds a synovial cavity of very irregular shape. The upper portion of the cavity intervenes between the under surfaces of the navicular, lunate, and triangular bones and the upper surfaces of the bones of the second row. It sends two prolongations upward—between the navicular and lunate, and the lunate and triangular—and three prolongations downward between the four bones of the second row. The prolongation between the greater and lesser multangulares, or that between the lesser multangular and capitate, is, owing to the absence of the interosseous ligament, often continuous with the cavity of the carpometacarpal joints, sometimes of the second, third, fourth, and fifth metacarpal bones, sometimes of the second and third only. In the latter condition the joint between the hamate and the fourth and fifth metacarpal bones has a separate synovial membrane. The synovial cavities of these joints are prolonged for a short distance between the bases of the metacarpal bones. There is a separate synovial membrane between the pisiform and triangular.

Movements.—The articulation of the hand and wrist considered as a whole involves four articular surfaces: (a) the inferior surfaces of the radius and articular disk; (b) the superior surfaces of the navicular, lunate, and triangular, the pisiform having no essential part in the movement of the hand; (c) the S-shaped surface formed by the inferior surfaces of the navicular, lunate, and triangular; (d) the reciprocal surface formed by the upper surfaces of the bones of the second row. These four surfaces form two joints: (1) a proximal, the wrist-joint proper; and (2) a distal, the mid-carpal joint.

1. The wrist-joint proper is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than of flexion is permitted, since the articulating surfaces extend farther on the dorsal than on the volar surfaces of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. The former is considerably greater in extent than the latter on account of the shortness of the styloid process of the ulna, abduction being soon limited by the contact of the styloid process of the radius with the greater multangular. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist.¹ Finally, circumduction is permitted by the combined and consecutive movements of adduction, extension, abduction, and flexion. No rotation is possible, but the effect of rotation is obtained by the pronation and supination of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; *extension* by the Extensores carpi radiales longus and brevis and the Extensor carpi ulnaris; *adduction* (ulnar flexion) by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion) by the Abductor pollicis longus, the Extensors of the thumb, and the Extensores carpi radiales longus and brevis and the Flexor carpi radialis. When the fingers are extended, flexion of the wrist is performed by the Flexores carpi radiales and ulnaris and extension by the Extensor digitorum communis. When the fingers are flexed, flexion of the wrist is performed by the Flexores digitorum sublimis and profundus, and extension by the Extensores carpi radiales and ulnaris.

¹ H. M. Johnston (Journal of Anatomy and Physiology, vol. xli) maintains that in ulnar and radial flexion only slight lateral movement occurs at the radiocarpal joint, and that in complete flexion and extension of the hand there is a small degree of ulnar flexion at the radiocarpal joint.

2. The chief movements permitted in the mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which are the movements most freely enjoyed, the greater and lesser multangulars on the radial side and the hamate on the ulnar side glide forward and backward on the navicular and triangular respectively, while the head of the capitate and the superior surface of the hamate rotate in the cup-shaped cavity of the navicular and lunate. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the capitate rotating around a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral and medial portions of the joint.

VIII. Carpometacarpal Articulations (*Articulationes Carpometacarpeae*).

Carpometacarpal Articulation of the Thumb (*articulatio carpometacarpea pollicis*).

—This is a joint of reciprocal reception between the first metacarpal and the greater multangular; it enjoys great freedom of movement on account of the configuration of its articular surfaces, which are saddle-shaped. The joint is surrounded by a capsule, which is thick but loose, and passes from the circumference of the base of the metacarpal bone to the rough edge bounding the articular surface of the greater multangular; it is thickest laterally and dorsally, and is lined by synovial membrane.

Movements.—In this articulation the movements permitted are flexion and extension in the plane of the palm of the hand, abduction and adduction in a plane at right angles to the palm, circumduction, and opposition. It is by the movement of opposition that the tip of the thumb is brought into contact with the volar surfaces of the slightly flexed fingers. This movement is effected through the medium of a small sloping facet on the anterior lip of the saddle-shaped articular surface of the greater multangular. The Flexor muscles pull the corresponding part of the articular surface of the metacarpal bone on to this facet, and the movement of opposition is then carried out by the Adductors.

Flexion of this joint is produced by the Flexores pollicis longus and brevis, assisted by the Opponens pollicis and the Adductor pollicis. Extension is effected mainly by the abductor pollicis longus, assisted by the Extensores pollicis longus and brevis. Adduction is carried out by the Adductor; abduction mainly by the Abductores pollicis longus and brevis, assisted by the Extensors.

Articulations of the Other Four Metacarpal Bones with the Carpus (*articulationes carpometacarpeae*).—The joints between the carpus and the second, third, fourth, and fifth metacarpal bones are arthrodial. The bones are united by dorsal, volar, and interosseous ligaments.

The Dorsal Ligaments (*ligamenta carpometacarpea dorsalia*).—The dorsal ligaments, the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surfaces. The second metacarpal bone receives two fasciculi, one from the greater, the other from the lesser multangular; the third metacarpal receives two, one each from the lesser multangular and capitate; the fourth two, one each from the capitate and hamate; the fifth receives a single fasciculus from the hamate, and this is continuous with a similar ligament on the volar surface, forming an incomplete capsule.

The Volar Ligaments (*ligamenta carpometacarpea volaria; palmar ligaments*).—The volar ligaments have a somewhat similar arrangement, with the exception of those of the third metacarpal, which are three in number: a lateral one from the greater multangular, situated superficial to the sheath of the tendon of the Flexor carpi radialis; and intermediate one from the capitate; and a medial one from the hamate.

The Interosseous Ligaments.—The interosseous ligaments consist of short, thick fibres, and are limited to one part of the carpometacarpal articulation; they connect the contiguous inferior angles of the capitate and hamate with the adjacent surfaces of the third and fourth metacarpal bones.

Synovial Membrane.—The synovial membrane is a continuation of that of the intercarpal joints. Occasionally, the joint between the hamate and the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (Fig. 458) are thus seen to be five in number. The *first* passes from the lower end of the ulnar to the ulnar notch of the radius, and lines the upper surface of the articular disk. The *second* passes from the articular disk and the lower end of the radius above, to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones, and sometimes, in the event of one of the interosseous ligaments being absent, between the bones of the second row to the carpal extremities of the second, third, fourth, and fifth metacarpal bones. The *fourth* extends from the margin of the greater multangular to the metacarpal bone of the thumb. The *fifth* runs between the adjacent margins of the triangular and pisiform bones. Occasionally the fourth and fifth carpo-metacarpal joints have a separate synovial membrane.

Movements.—The movements permitted in the carpometacarpal articulations of the fingers are limited to slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. The metacarpal bone of the little finger is most movable, then that of the ring finger; the metacarpal bones of the index and middle fingers are almost immovable.

IX. Intermetacarpal Articulations (Articulationes Intermetacarpeae; Articulations of the Metacarpal Bones with Each Other).

The bases of the second, third, fourth and fifth metacarpal bones articulate with one another by small surfaces covered with cartilage, and are connected together by dorsal, volar, and interosseous ligaments.

The *dorsal* (*ligamenta basium oss. metacarp. dorsalia*) and *volar ligaments* (*ligamenta basium oss. metacarp. volaria*; *palmar ligaments*) pass transversely from one bone to another on the dorsal and volar surfaces. The *interosseous ligaments* (*ligamenta basium oss. metacarp. interossea*) connect their contiguous surfaces, just distal to their collateral articular facets.

The *synovial membrane* for these joints is continuous with that of the carpometacarpal articulations.

The Transverse Metacarpal Ligament (*ligamentum capitulorum* [*oss. metacarpalium*] *transversum*) (Fig. 459).—This ligament is a narrow fibrous band, which runs across the volar surfaces of the heads of the second, third, fourth and fifth metacarpal bones, connecting them together. It is blended with the volar (glenoid) ligaments of the metacarpophalangeal articulations. Its volar surface is concave where the Flexor tendons pass over it; behind it the tendons of the Interossei pass to their insertions.

X. Metacarpophalangeal Articulations (Articulationes Metacarpophalangeae; Metacarpophalangeal Joints) (Figs. 459, 460).

These articulations are of the condyloid kind, formed by the reception of the rounded heads of the metacarpal bones into shallow cavities on the proximal ends of the first phalanges, with the exception of that of the thumb, which presents more of the characters of a ginglymoid joint. Each joint has a volar and two collateral ligaments.

The Volar Ligaments (*glenoid ligaments of Cruveilhier*; *palmar or vaginal ligaments*).—The volar ligaments are thick, dense, fibrocartilaginous structures, placed upon the volar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected; they are loosely united to the metacarpal bones, but are very firmly attached to the bases of the first phalanges. Their volar surfaces are intimately blended with the transverse metacarpal ligament, and present grooves for the passage of the Flexor tendons, the sheaths surrounding which are connected to the sides of the grooves. Their deep surfaces form parts of the articular facets for the heads of the metacarpal bones, and are lined by synovial membranes.

The Collateral Ligaments (*ligamenta collateralia*; *lateral ligaments*).—The collateral ligaments are strong, rounded cords, placed on the sides of the joints; each is attached by one extremity to the posterior tubercle and adjacent depres-

sion on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

The dorsal surfaces of these joints are covered by the expansions of the Extensor tendons, together with some loose areolar tissue which connects the deep surfaces of the tendons to the bones.

FIG. 459.—Metacarpophalangeal articulation and articulations of digit. Volar aspect.

FIG. 460.—Metacarpophalangeal articulation and articulations of digit. Ulnar aspect.

Movements.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the movements of abduction and adduction are very limited, and cannot be performed when the fingers are flexed.

II. Articulations of the Digits (*Articulationes Digitorum Manus; Interphalangeal Joints*) (Figs. 459, 460).

The interphalangeal articulations are hinge-joints; each has a volar and two collateral ligaments. The arrangement of these ligaments is similar to those in the metacarpophalangeal articulations. The Extensor tendons supply the place of posterior ligaments.

Movements.—The only movements permitted in the interphalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The amount of flexion is very considerable, but extension is limited by the volar and collateral ligaments.

Muscles Acting on the Joints of the Digits.—Flexion of the metacarpophalangeal joints of the fingers is effected by the *Flexores digitorum sublimis* and *profundus*, *Lumbricales*, and *Interossei*, assisted in the case of the little finger by the *Flexor digiti quinti brevis*. Extension is produced

by the Extensor digitorum communis, Extensor indicis proprius, and Extensor digiti quinti proprius.

Flexion of the interphalangeal joints of the fingers is accomplished by the Flexor digitorum profundus acting on the proximal and distal joints and by the Flexor digitorum sublimis acting on the proximal joints. Extension is effected mainly by the Lumbricales and Interossei, the long Extensors having little or no action upon these joints.

Flexion of the metacarpophalangeal joint of the thumb is effected by the Flexores pollicis longus and brevis; extension by the Extensores pollicis longus and brevis. Flexion of the interphalangeal joint is accomplished by the Flexor pollicis longus, and extension by the Extensor pollicis longus.

ARTICULATIONS OF THE LOWER EXTREMITY.

The articulations of the Lower Extremity comprise the following:

- | | |
|----------------------------------|----------------------------|
| I. Hip. | V. Intertarsal. |
| II. Knee. | VI. Tarsometatarsal. |
| III. Tibiofibular. | VII. Intermetatarsal. |
| IV. Ankle. | VIII. Metatarsophalangeal. |
| IX. Articulations of the Digits. | |

I. Coxal Articulation or Hip-joint (*Articulatio Coxae*).

This articulation is an enarthrodial or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articular cartilage on the head of the femur, thicker at the centre than at the circumference, covers the entire surface with the exception of the fovea capitis femoris, to which the ligamentum teres is attached; that on the acetabulum forms an incomplete marginal ring, the lunate surface. Within the lunate surface there is a circular depression devoid of cartilage, occupied in the recent state by a mass of fat, covered by synovial membrane. The ligaments of the joint are:

- | | |
|------------------------|-------------------------------|
| The Articular Capsule. | The Pubocapsular. |
| The Iliofemoral. | The Ligamentum Teres Femoris. |
| The Ischiocapsular. | The Glenoidal Labrum. |

The Transverse Acetabular

The Articular Capsule (*capsula articularis*; *capsular ligament*) (Figs. 442, 443).—The articular capsule is strong and dense. *Above*, it is attached to the margin of the acetabulum 5 to 6 mm. beyond the glenoidal labrum behind; but in *front*, it is attached to the outer margin of the labrum, and, opposite to the notch where the margin of the cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. It surrounds the neck of the femur, and is attached, in *front*, to the intertrochanteric line; *above*, to the base of the neck; *behind*, to the neck, about 1.25 cm. above the intertrochanteric crest; *below*, to the lower part of the neck, close to the lesser trochanter. From its femoral attachment some of the fibres are reflected upward along the neck as longitudinal bands, termed *retinacula*. The capsule is much thicker at the upper and forepart of the joint, where the greatest amount of resistance is required; behind and below, it is thin and loose. It consists of two sets of fibres, circular and longitudinal. The circular fibres, *zona orbicularis*, are most abundant at the lower and back part of the capsule (Fig. 463), and form a sling or collar around the neck of the femur. Anteriorly they blend with the deep surface of the iliofemoral ligament, and gain an attachment to the anterior inferior iliac spine. The longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they are reinforced by distinct bands, or accessory ligaments, of which the most important is the *iliofemoral ligament*. The other accessory bands are known

as the **pubocapsular** and the **ischiocapsular ligaments**. The external surface of the capsule is rough, covered by numerous muscles, and separated in front from the Psoas major and Iliacus by a bursa, which not infrequently communicates by a circular aperture (Fig. 442) with the cavity of the joint.

The Iliofemoral Ligament (*ligamentum iliofemorale*; *Y-ligament*; *ligament of Bigelow*) (Fig. 461).—The iliofemoral ligament is a band of great strength which lies in front of the joint; it is intimately connected with the capsule, and serves to strengthen it in this situation. It is attached, *above*, to the lower part of the anterior inferior iliac spine; *below*, it divides into two bands, one of which passes downward and is fixed to the lower part of the intertrochanteric line; the other is directed downward and lateralward and is attached to the upper part of the

Intert

FIG. 461.—Right hip-joint from the front (Spalteholz)

same line. Between the two bands is a thinner part of the capsule. In some cases there is no division, and the ligament spreads out into a flat triangular band which is attached to the whole length of the intertrochanteric line. This ligament is frequently called the Y-shaped ligament of Bigelow; and its upper band is sometimes named the **iliotrochanteric ligament**.

The Pubocapsular Ligament (*ligamentum pubocapsulare*; *pubofemoral ligament*).—This ligament is attached, *above*, to the obturator crest and the superior ramus of the pubis; *below*, it blends with the capsule and with the deep surface of the vertical band of the iliofemoral ligament.

The Ischiocapsular Ligament (*ligamentum ischiocapsulare*; *ischiocapsular band*; *ligament of Bertin*).—The ischiocapsular ligament consists of a triangular band of strong fibres, which spring from the ischium below and behind the acetabulum, and blend with the circular fibres of the capsule.

The Ligamentum Teres Femoris (Fig. 462).—The ligamentum teres femoris is a triangular, somewhat flattened band implanted by its apex into the antero-superior part of the fovea capitis femoris; its base is attached by two bands, one into either side of the acetabular notch, and between these bony attachments it blends with the transverse ligament. It is ensheathed by the synovial membrane, and varies greatly in strength in different subjects; occasionally only the synovial fold exists, and in rare cases even this is absent. The ligament is made tense when the thigh is semiflexed and the limb then adducted or rotated outward; it is, on the other hand, relaxed when the limb is abducted. It has, however, but little influence as a ligament.

FIG. 462.—Left hip-joint, opened by removing the floor of the acetabulum from within the pelvis.

The Glenoidal Labrum (*labrum glenoidale; cotyloid ligament*).—The glenoidal labrum is a fibrocartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the same time it protects the edge of the bone, and fills up the inequalities of its surface. It bridges over the notch as the **transverse ligament**, and thus forms a complete circle, which closely surrounds the head of the femur and assists in holding it in its place. It is triangular on section, its base being attached to the margin of the acetabulum, while its opposite edge is free and sharp. Its two surfaces are invested by synovial membrane, the external one being in contact with the capsule, the internal one being inclined inward so as to narrow the acetabulum, and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front, and consists of compact fibres.

The Transverse Acetabular Ligament (*ligamentum transversum acetabuli; transverse ligament*).—This ligament is in reality a portion of the glenoidal labrum, though differing from it in having no cartilage cells among its fibres. It consists of strong,

flattened fibres, which cross the acetabular notch, and convert it into a foramen through which the nutrient vessels enter the joint.

Synovial Membrane (Fig. 463).—The synovial membrane is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers the portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsule, covers both surfaces of the glenoidal labrum and the mass of fat contained in the depression at the bottom of the acetabulum, and ensheathes the ligamentum teres as far as the head of the femur. The joint cavity sometimes communicates through a hole in the capsule between the vertical band of the iliofemoral ligament and the pubocapsular ligament with a bursa situated on the deep surfaces of the Psoas major and Iliacus.

FIG. 463.—Capsule of hip-joint (distended). Posterior aspect.

The **muscles** in relation with the joint are, in *front*, the Psoas major and Iliacus, separated from the capsule by a bursa; *above*, the reflected head of the Rectus femoris and Glutæus minimus, the latter being closely adherent to the capsule; *medially*, the Obturator externus and Pectineus; *behind*, the Piriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris (Fig. 464).

The **arteries** supplying the joint are derived from the obturator, medial femoral circumflex, and superior and inferior gluteals.

The **nerves** are articular branches from the sacral plexus, sciatic, obturator, accessory obturator, and a filament from the branch of the femoral supplying the Rectus femoris.

Movements.—The movements of the hip are very extensive, and consist of flexion, extension, adduction, abduction, circumduction, and rotation.

The length of the neck of the femur and its inclinations to the body of the bone have the effect of converting the angular movements of flexion, extension, adduction, and abduction partially into rotatory movements in the joint. Thus when the thigh is flexed or extended, the head of the femur, on account of the *medial* inclination of the neck, rotates within the acetabulum with only a slight amount of gliding to and fro. The *forward* slope of the neck similarly affects the movements of adduction and abduction. Conversely rotation of the thigh which is permitted by the *upward* inclination of the neck, is not a simple rotation of the head of the femur in the acetabulum, but is accompanied by a certain amount of gliding.

The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as has been seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsule. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for an area extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the glenoidal labrum, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided. The iliofemoral ligament is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and therefore the pelvis tends to fall backward, but is prevented by the tension of the iliofemoral ligaments. The security of the joint may be provided for also by the two bones being directly united through the ligamentum teres; but it is doubtful whether this ligament has much influence upon the mechanism

Femoral artery

)

Obturator internus

FIG. 464.—Structures surrounding right hip-joint.

of the joint. When the knee is flexed, flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact, and when the knee is extended, by the action of the hamstring muscles; extension is checked by the tension of the iliofemoral ligament; adduction by the thighs coming into contact; adduction with flexion by the lateral band of the iliofemoral ligament and the lateral part of the capsule; abduction by the medial band of the iliofemoral ligament and the pubocapsular ligament; rotation outward by the lateral band of the iliofemoral ligament; and rotation inward by the ischiocapsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are the Psoas major, Iliacus, Rectus femoris, Sartorius, Pectineus, Adductores longus and brevis, and the anterior fibres of the Glutaei medius and minimus. *Extension* is mainly performed by the Glutaeus maximus, assisted by the hamstring muscles and the ischial head of the Adductor magnus. The thigh is *adducted* by the Adductores magnus, longus, and brevis, the Pectineus, the Gracilis, and lower part of the Glutaeus maximus, and *abducted* by the Glutaei medius and minimus, and the upper part of the Glutaeus maximus. The muscles which *rotate* the thigh *inward* are the Glutaeus minimus and the anterior fibres of the Glutaeus medius, the Tensor fasciae latae and the Iliacus and Psoas major; while

those which rotate it *outward* are the posterior fibres of the *Glutaeus medius*, the *Piriformis*, *Obturator externus* and *internus*, *Gemelli superior* and *inferior*, *Quadratus femoris*, *Glutaeus maximus*, the *Adductores longus*, *brevis*, and *magnus*, the *Pectineus*, and the *Sartorius*.

Applied Anatomy.—In dislocation of the hip, "the head of the thigh bone may rest at any point around its socket" (Bryant); but whatever position it ultimately assumes, the primary displacement is generally downward and medialward, the capsule giving way at its weakest—that is, its lower and medial—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the iliofemoral ligament, which is not easily ruptured. When, for instance, the head of the bone is forced backward, this ligament forms a fixed axis, around which the head of the bone rotates, and is thus driven on to the dorsum of the ilium. The iliofemoral ligament also influences the position of the thigh in the various dislocations; in the dislocations backward it is tense, and produces inversion of the limb; in the dislocation on to the pubis, it is relaxed, and therefore allows the external rotators to evert the thigh; while in dislocation into the obturator foramen it is tense, and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the *Obturator internus*, have very little direct influence in determining the position of the head of the bone. Bigelow, however, has endeavored to show that the *Obturator internus* is the principal agent in deciding whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium, or in or near the greater sciatic notch; in both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the displacement on to the dorsum the head of the bone travels up behind the acetabulum, in front of the muscle; while in the dislocation into the greater sciatic notch the head passes behind the muscle, and is prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and it therefore remains in the neighborhood of the notch. Bigelow distinguishes these two forms of dislocation by describing them as dislocations backward, "above and below" the *Obturator internus*.

The iliofemoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as the fulcrum to a lever, of which the long arm is the body of the femur, and the short arm the neck of the bone (Fig. 465).

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of bacterial infections, as in rheumatism, pyemia, etc. When, in these cases, effusion takes place, and the joint is distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just medial to the iliofemoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much oftener of a chronic character, and is usually of tuberculous origin. It begins usually in the bone, and, in most cases, in the growing, highly vascular tissue in the neighborhood of the epiphysal cartilage of the femoral head. In this respect it differs very materially from tuberculous arthritis of the knee, where the disease usually commences in the synovial membrane.

In chronic hip disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case, the limb is flexed, abducted, and rotated outward. In this position all the ligaments of the joint are relaxed; the front of the capsule by flexion; the lateral band of the iliofemoral ligament by abduction; and the medial band of this ligament and the back of the capsule by rotation outward. It is, therefore, the position of greatest ease. The condition is not quite obvious at first, upon examining a patient. If the patient be laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be seen that the pelvis is tilted downward on the diseased side and the limb apparently longer than its fellow, and that the lumbar portion of the vertebral column is arched forward (lordosis). The condition is thus explained: a limb which is flexed and abducted is obviously useless for progression, and in order to overcome the difficulty the

FIG. 465.—Hip-joint, showing the iliofemoral ligament. (After Bigelow.)

patient depresses the affected side of his pelvis, thus producing parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downward, instead of forward. In the later stages of the disease the limb becomes flexed and adducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex spasm by the irritation of the peripheral terminations of this nerve in the inflamed articulation.

Osteoarthritis is common in the hip-joint, and more so in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or advanced life. When much deformity is associated with chronic osteoarthritis the condition is spoken of as *arthritis deformans of the hip*, or *morbus coxae senilis*. The head of the femur is worn away, and after it often the neck too, until a new irregular articular surface is produced, around which a new formation of bone occurs, and also about the edges of the acetabulum, which is widened and eroded by a similar chronic process. Pain in the joint, shortening of the limb, and great limitation of movement result, with much creaking and grating when the joint is moved.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior or a posterior incision. The former entails less interference with important structures, especially muscles, than the latter, but permits of less efficient drainage. In the operation from the front, an incision is made 8 to 10 cm. in length, starting immediately below and lateral to the anterior superior iliac spine, downward between the Sartorius and Tensor fasciae latae, to the neck of the bone, dividing the capsule at its upper part. The neck of the femur is then divided, and the head of the bone extracted. All diseased tissue is carefully removed with a sharp spoon or scissors, and the cavity thoroughly flushed out with a hot antiseptic or sterile fluid. The posterior method consists in making an incision 8 to 10 cm. long commencing midway between the top of the greater trochanter and the iliac crest, and extending down the posterior border of the trochanter. The muscles are detached from the greater trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and as much affected bone removed as is thought necessary. The head of the bone is then levered out of the acetabulum.

II. The Knee-joint (Articulatio Genu).

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: two condyloid joints, one between each condyle of the femur and the corresponding meniscus and condyle of the tibia; and a third between the patella and the femur, partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where, corresponding to these three subdivisions, three synovial cavities are sometimes found, either entirely distinct or only connected together by small communications. This view is further rendered probable by the existence in the middle of the joint of the two cruciate ligaments, which must be regarded as the collateral ligaments of the medial and lateral joints. The existence of the patellar fold of synovial membrane would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to the lateral and the other to the medial joint.

The bones are connected together by the following ligaments:

The Articular Capsule.	The Anterior Cruciate.
The Ligamentum Patellae.	The Posterior Cruciate.
The Oblique Popliteal.	The Medial and Lateral Menisci.
The Tibial Collateral.	The Transverse.
The Fibular Collateral.	The Coronary.

The Articular Capsule (*capsula articularis*; *capsular ligament*) (Fig. 466).—The articular capsule consists of a thin, but strong, fibrous membrane which is strengthened in almost its entire extent by bands inseparably connected with it. Above

and in front, beneath the tendon of the Quadriceps femoris, it is represented only by the synovial membrane. Its chief strengthening bands are derived from the fascia lata and from the tendons surrounding the joint. In front, expansions from the Vasti and from the fascia lata and its iliotibial band fill in the intervals between the anterior and collateral ligaments, constituting the **medial and lateral patellar retinacula**. Behind the capsule consists of vertical fibres which arise from the condyles and from the sides of the intercondyloid fossa of the femur; the posterior part of the capsule is therefore situated on the sides of and in front of the cruciate ligaments, which are thus excluded from the joint cavity. Behind the cruciate ligaments is the oblique popliteal ligament which is augmented by fibres derived from the tendon of the Semimembranosus. Laterally, a prolongation from the iliotibial band fills in the interval between the oblique popliteal and the fibular collateral ligaments, and partly covers the latter. Medially, expansions from the Sartorius and Semimembranosus pass upward to the tibial collateral ligament and strengthen the capsule.

The Ligamentum Patellae (*anterior ligament*) (Fig. 466).—The ligamentum patellae is the central portion of the common tendon of the Quadriceps femoris, which is continued from the patella to the tuberosity of the tibia. It is a strong, flat, ligamentous band, about 8 cm. in length, attached, *above*, to the apex and adjoining margins of the patella and the rough depression on its posterior surface; *below*, to the tuberosity of the tibia; its superficial fibres are continuous over the front of the patella with those of the tendon of the Quadriceps femoris. The medial and lateral portions of the tendon of the Quadriceps pass down on either side of the patella, to be inserted into the upper extremity of the tibia on either side of the tuberosity; these portions merge into the capsule, as stated above, forming the medial and lateral patellar retinacula. The posterior surface of the ligamentum patellae is separated from the synovial membrane of the joint by a large infrapatellar pad of fat, and from the tibia by a bursa.

FIG. 466.—Right knee-joint. Anterior view.

The Oblique Popliteal Ligament (*ligamentum popliteum obliquum; posterior ligament*) (Fig. 467).—This ligament is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached *above* to the upper margin of the intercondyloid fossa and posterior surface of the femur close to the articular margins of the condyles, and *below* to the posterior margin of the head of the tibia. Superficial to the main part of the ligament is a strong fasciculus, derived from the tendon of the Semimembranosus and passing from the back part of the medial condyle of the tibia obliquely upward and lateralward to the back part of the lateral condyle of the femur. The oblique popliteal ligament forms part of the floor of the popliteal fossa, and the popliteal artery rests upon it.

The Tibial Collateral Ligament (*ligamentum collaterale tibiale; internal lateral ligament*) (Fig. 466).—The tibial collateral is a broad, flat, membranous band, situated nearer to the back than to the front of the joint. It is attached, *above*, to the medial

condyle of the femur immediately below the adductor tubercle; *below*, to the medial condyle and medial surface of the body of the tibia. The fibres of the posterior part of the ligament are short and incline backward as they descend; they are inserted into the tibia above the groove for the Semimembranosus. The anterior part of the ligament is a flattened band, about 10 cm. long, which inclines forward as it descends. It is inserted into the medial surface of the body of the tibia about 2.5 cm. below the level of the condyle. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semitendinosus, a bursa being interposed. Its deep surface covers the inferior medial genicular vessels and nerve and the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres; it is intimately adherent to the medial meniscus.

FIG. 467.—Right knee-joint. Posterior view

FIG. 468.—Right knee-joint, from the front, showing interior ligaments.

The Fibular Collateral Ligament (*ligamentum collaterale fibulare; external lateral or long external lateral ligament*) (Fig. 469).—The fibular collateral is a strong, rounded, fibrous cord, attached, *above*, to the back part of the lateral condyle of the femur, immediately above the groove for the tendon of the Popliteus; *below*, to the lateral side of the head of the fibula, in front of the styloid process. The greater part of its lateral surface is covered by the tendon of the Biceps femoris; the tendon, however, divides at its insertion into two parts, which are separated by the ligament. Deep to the ligament are the tendon of the Popliteus, and the inferior lateral genicular vessels and nerve. The ligament has no attachment to the lateral meniscus.

An inconstant bundle of fibres, the **short fibular collateral ligament**, is placed behind and parallel with the preceding, attached, *above*, to the lower and back part of the lateral condyle of the femur; *below*, to the summit of the styloid process of the fibula. Passing deep to it are the tendon of the Popliteus, and the inferior lateral genicular vessels and nerve.

The Cruciate Ligaments (*ligamenta cruciata genu; crucial ligaments*).—The cruciate ligaments are of considerable strength, situated in the middle of the joint, nearer to its posterior than to its anterior surface. They are called *cruciate* because they cross each other somewhat like the lines of the letter X; and have received the names *anterior* and *posterior*, from the position of their attachments to the tibia.

The Anterior Cruciate Ligament (*ligamentum cruciatum anterius; external crucial ligament*) (Fig. 468) is attached to the depression in front of the intercondyloid eminence of the tibia, being blended with the anterior extremity of the lateral meniscus; it passes upward, backward, and lateralward, and is fixed into the medial and back part of the lateral condyle of the femur.

Tibial collateral
ligament

FIG. 469.—Left knee-joint from behind, showing interior ligaments.

The Posterior Cruciate Ligament (*ligamentum cruciatum posterius; internal crucial ligament*) (Fig. 469) is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the posterior intercondyloid fossa of the tibia, and to the posterior extremity of the lateral meniscus; and passes upward, forward, and medialward, to be fixed into the lateral and front part of the medial condyle of the femur.

The Menisci (*semilunar fibrocartilages*) (Fig. 470).—The menisci are two crescentic lamellæ, which serve to deepen the surfaces of the head of the tibia for articulation with the condyles of the femur. The peripheral border of each meniscus is thick, convex, and attached to the inside of the capsule of the joint; the opposite border is thin, concave, and free. The upper surfaces of the menisci are concave, and in contact with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia; both surfaces are smooth, and invested by synovial membrane. Each meniscus covers approximately the peripheral two-thirds of the corresponding articular surface of the tibia.

The **medial meniscus** (*meniscus medialis; internal semilunar fibrocartilage*) is nearly semicircular in form, a little elongated from before backward, and broader behind than in front; its anterior end, thin and pointed, is attached to the anterior intercondyloid fossa of the tibia, in front of the anterior cruciate ligament; its posterior end is fixed to the posterior intercondyloid fossa of the tibia, between the attachments of the lateral meniscus and the posterior cruciate ligament.

Anterior cruciate ligament

Transverse ligament

FIG. 470.—Head of right tibia seen from above, showing menisci and attachments of ligaments.

The **lateral meniscus** (*meniscus lateralis; external semilunar fibrocartilage*) is nearly circular and covers a larger portion of the articular surface than the medial one. It is grooved laterally for the tendon of the Popliteus, which separates it from the fibular collateral ligament. Its anterior end is attached in front of the intercondyloid eminence of the tibia, lateral to, and behind, the anterior cruciate ligament, with which it blends; the posterior end is attached behind the intercondyloid eminence of the tibia and in front of the posterior end of the medial meniscus. The anterior attachment of the lateral meniscus is twisted on itself so that its free margin looks backward and upward, its anterior end resting on a sloping shelf of bone on the front of the lateral process of the intercondyloid eminence. Close to its posterior attachment it sends off a strong fasciculus, the **ligament of Wrisberg** (Figs. 469, 470), which passes upward and medialward, to be inserted into the medial condyle of the femur, immediately behind the attachment of the posterior cruciate ligament. Occasionally a small fasciculus passes forward to be inserted into the lateral part of the anterior cruciate ligament. The lateral meniscus gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The Transverse Ligament (*ligamentum transversum genu*).—The transverse ligament connects the anterior convex margin of the lateral meniscus to the anterior end of the medial meniscus; its thickness varies considerably in different subjects, and it is sometimes absent.

The **coronary ligaments** are merely portions of the capsule, which connect the periphery of each meniscus with the margin of the head of the tibia.

Synovial Membrane.—The synovial membrane of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a large cul-de-sac beneath the Quadriceps femoris (Figs. 471, 472) on the lower part of the front of the femur, and frequently communicates with a bursa interposed between the tendon and the front of the femur. The pouch of synovial membrane between the Quadriceps and front of the femur is supported, during the movements of the knee, by a small muscle, the *Articularis genu*, which

is inserted into it. On either side of the patella, the synovial membrane extends beneath the aponeuroses of the Vasti, and more especially beneath that of the Vastus medialis. Below the patella it is separated from the ligamentum patellae by a considerable quantity of fat, known as the **infrapatellar pad**. From the medial and lateral borders of the articular surface of the patella, reduplications of the synovial membrane project into the interior of the joint. These form two fringe-like folds termed the **alar folds**; below, these folds converge and are continued as a single band, the **patellar fold** (*ligamentum mucosum*), to the front of the intercondyloid fossa of the femur. On either side of the joint, the synovial membrane passes downward from the femur, lining the capsule to its point of attachment to the menisci; it may then be traced over the upper surfaces of these to their free borders, and thence along their under surfaces to the tibia (Figs. 472, 473).

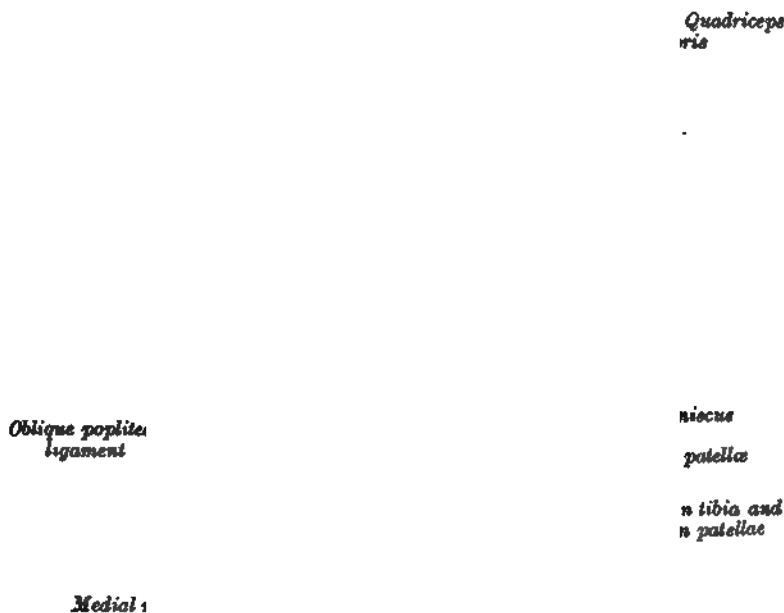

FIG. 471.—Sagittal section of right knee-joint.

At the back part of the lateral meniscus it forms a cul-de-sac between the groove on its surface and the tendon of the Popliteus; it is reflected across the front of the cruciate ligaments, which are therefore situated outside the synovial cavity.

Bursae.—The bursae near the knee-joint are the following: In front there are four bursae: a large one is interposed between the patella and the skin, a small one between the upper part of the tibia and the ligamentum patellae, a third between the lower part of the tuberosity of the tibia and the skin, and a fourth between the anterior surface of the lower part of the femur and the deep surface of the Quadriceps femoris, usually communicating with the knee-joint. Laterally there are four bursae: (1) one (which sometimes communicates with the joint) between the lateral head of the Gastrocnemius and the capsule; (2) one between the fibular collateral ligament

and the tendon of the Biceps; (3) one between the fibular collateral ligament and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one between the tendon of the Popliteus and the lateral condyle of the femur, usually an extension from the synovial membrane of the joint. Medially, there are five bursae: (1) one between the medial head of the Gastrocnemius and the capsule; this sends a prolongation between the tendon of the medial head of the Gastrocnemius and the tendon of the Semimembranosus and often communicates with the joint; (2) one superficial to the tibial collateral ligament, between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one deep to the tibial collateral ligament, between it and the tendon of the Semimembranosus (this is sometimes only an expansion from the next bursa); (4) one between the tendon of the Semimembranosus and the head of the tibia; (5) occasionally there is a bursa between the tendons of the Semimembranosus and Semitendinosus.

FIG. 472.—Capsule of right knee-joint (distended) Lateral aspect.

Structures Around the Joint.—In front, and at the sides, is the Quadriceps femoris; laterally the tendons of the Biceps femoris and Popliteus and the common peroneal nerve; medially, the Sartorius, Gracilis, Semitendinosus, and Semimembranosus; behind, the popliteal vessels, and the tibial nerve, Popliteus, Plantaris, and medial and lateral heads of the Gastrocnemius, some lymph glands, and fat.

The **arteries** supplying the joint are the highest genicular (anastomotica magna), a branch of the femoral, the genicular branches of the popliteal, the recurrent branches of the anterior tibial, and the descending branch from the lateral femoral circumflex of the profunda femoris.

The **nerves** are derived from the obturator, femoral, tibial, and common peroneal.

Movements. The movements which take place at the knee-joint are flexion and extension, and, in certain positions of the joint, internal and external rotation. The movements of flexion and extension at this joint differ from those in a typical hinge-joint, such as the elbow, in that (a) the axis around which motion takes place is not a fixed one, but shifts forward during extension and backward during flexion, (b) the commencement of flexion and the end of extension are accompanied by rotatory movements associated with the fixation of the limb in a position of

great stability. The movement from full flexion to full extension may therefore be described in three phases:

1. In the fully flexed condition the posterior parts of the femoral condyles rest on the corresponding portions of the meniscotibial surfaces, and in this position a slight amount of simple rolling movement is allowed.

2. During the passage of the limb from the flexed to the extended position a gliding movement is superposed on the rolling, so that the axis, which at the commencement is represented by a line through the inner and outer condyles of the femur, gradually shifts forward. In this part of the movement, the posterior two-thirds of the tibial articular surfaces of the two femoral condyles are involved, and as these have similar curvatures and are parallel to one another, they move forward equally.

FIG. 473.—Capsule of right knee-joint (distended) Posterior aspect.

3. The lateral condyle of the femur is brought almost to rest by the tightening of the anterior cruciate ligament; it moves, however, slightly forward and medialward, pushing before it the anterior part of the lateral meniscus. The tibial surface on the medial condyle is prolonged farther forward than that on the lateral, and this prolongation is directed lateralward. When, therefore, the movement forward of the condyles is checked by the anterior cruciate ligament, continued muscular action causes the medial condyle, dragging with it the meniscus, to travel backward and medialward, thus producing an internal rotation of the thigh on the leg. When the position of full extension is reached the lateral part of the groove on the lateral condyle is pressed against the anterior part of the corresponding meniscus, while the medial part of the groove rests on the articular margin in front of the lateral process of the tibial intercondyloid eminence. Into the groove on the medial condyle is fitted the anterior part of the medial meniscus, while the anterior cruciate ligament and the articular margin in front of the medial process of the tibial intercondyloid eminence are received into the forepart of the intercondyloid fossa of the femur. This third phase by which all these parts are brought into accurate apposition is known as the "screwing home," or locking movement of the joint.

The complete movement of flexion is the converse of that described above, and is therefore preceded by an external rotation of the femur which unlocks the extended joint.

The axes around which the movements of flexion and extension take place are not precisely at right angles to either bone; in flexion, the femur and tibia are in the same plane, but in extension the one bone forms an angle, opening lateralward with the other.

In addition to the rotatory movements associated with the completion of extension and the initiation of flexion, rotation inward or outward can be effected when the joint is partially flexed; these movements take place mainly between the tibia and the menisci, and are freest when the leg is bent at right angles with the thigh.

Movements of Patella.—The articular surface of the patella is indistinctly divided into seven facets—upper, middle, and lower horizontal pairs, and a medial perpendicular facet (Fig. 474).

When the knee is forcibly flexed, the medial perpendicular facet is in contact with the semilunar surface on the lateral part of the medial condyle; this semilunar surface is a prolongation backward of the medial part of the patellar surface. As the leg is carried from the flexed to the extended position, first the highest pair, then the middle pair, and lastly the lowest pair of horizontal facets is successively brought into contact with the patellar surface of the femur. In the extended position, when the Quadriceps femoris is relaxed, the patella lies loosely on the front of the lower end of the femur.

During flexion, the ligamentum patellae is put upon the stretch, and in extreme flexion the posterior cruciate ligament, the oblique popliteal, and collateral ligaments, and, to a slight extent, the anterior cruciate ligament, are relaxed. Flexion is checked during life by the contact of the leg with the thigh. When the knee-joint is fully extended the oblique popliteal and collateral ligaments,

FIG. 474.—Posterior surface of the right patella, showing diagrammatically the areas of contact with the femur in different positions of the knee.

the anterior cruciate ligament, and the posterior cruciate ligament, are rendered tense; in the act of extending the knee, the ligamentum patellae is tightened by the Quadriceps femoris, but in full extension with the heel supported it is relaxed. Rotation inward is checked by the anterior cruciate ligament; rotation outward tends to uncruciate and relax the cruciate ligaments, but is checked by the tibial collateral ligament. The main function of the cruciate ligament is to act as a direct bond between the tibia and femur and to prevent the former bone from being carried too far backward or forward. They also assist the collateral ligaments in resisting any bending of the joint to either side. The menisci are intended, as it seems, to adapt the surfaces of the tibia to the shape of the femoral condyles to a certain extent, so as to fill up the intervals which would otherwise be left in the varying positions of the joint, and to obviate the jars which would be so frequently transmitted up the limb in jumping or by falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the front of the knee-joint, and distributes upon a large and tolerably even surface, during kneeling, the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps femoris.

When standing erect in the attitude of "attention," the weight of the body falls in front of a line carried across the centres of the knee-joints, and therefore tends to produce overextension of the articulations; this, however, is prevented by the tension of the anterior cruciate, oblique popliteal, and collateral ligaments.

Extension of the leg on the thigh is performed by the Quadriceps femoris; *flexion* by the Biceps femoris, Semitendinosus, and Semimembranosus, assisted by the Gracilis, Sartorius, Gastrocnemius, Popliteus, and Plantaris. *Rotation outward* is effected by the Biceps femoris, and *rotation inward* by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis. The Popliteus comes into action especially at the commencement of the movement of flexion of the knee; by its contraction the leg is rotated inward, or, if the tibia be fixed, the thigh is rotated outward, and the knee-joint is unlocked.

Applied Anatomy.—From a consideration of the construction of the knee-joint, it would at first sight appear to be one of the least secure joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is considerable; the articular surfaces are but ill-adapted to each other, and the range of motion which it enjoys is great. All these circumstances tend to render the articulation insecure; nevertheless on account of the powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumatism is a rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is liable to occur, and is frequently brought about by the action of the muscles.

One or other of the menisci may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The meniscus may be displaced either medialward or lateralward; that is to say, either toward the tibial intercondyloid eminence, so that the cartilage becomes lodged in the intercondyloid fossa; or to one side, so that the cartilage projects beyond the margin of the two articular surfaces. The medial meniscus is much more commonly affected than the lateral.

Acute synovitis, the result of traumatism, is of frequent occurrence in the knee, on account of

the superficial position of the joint. When the cavity is distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about 2.5 cm., occasionally 5 cm. or more, above the patellar surface of the femur, and extending a little higher under the Vastus medialis than under the Vastus lateralis. The lower level of the synovial membrane is just at the level of the head of the tibia. Chronic synovitis shows itself principally in the form of pulpy degeneration of the synovial membrane, the result of tuberculous infection. Syphilitic disease with gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteoarthritis, and is more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilages is almost confined to the knee, though they are occasionally met with in other joints. Many of them occur in cases of osteoarthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, only in the former case meriting the usual term, "loose" cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the menisci becomes detached and constitutes the foreign body.

In inflammatory affections of the knee-joint, the position of greatest ease, and therefore the one which is always assumed, is that of slight flexion. In this position there is the most complete relaxation of ligamentous structures, and, therefore, the greatest diminution in the tension caused by the effusion. If this flexed position be maintained for any length of time, it becomes permanent from fibrous adhesions taking place, and the utility of the limb is materially impaired. Attention should therefore be paid by the surgeon to the position of the limb; and by carefully applied splints, with the leg in an extended position, this untoward result should be prevented. In cases of septic synovitis, incisions to evacuate the pus should be made vertically on either side of the patella, between it and the condyles of the femur.

Genu valgum, or knock-knee, is a common deformity of childhood. In this condition, as the patient stands, the medial condyles of the two femora are in contact, but the two medial malleoli are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the tibial collateral ligament and other fibrous structures on the medial side of the joint; as a result of this there is a constant undue pressure of the lateral condyle of the tibia against the lateral condyle of the femur. This pressure causes arrest of growth, and, possibly, wasting of the lateral condyle, and a consequent tendency for the tibia to become separated from the medial condyle of the femur. Irregular overgrowth from the medial portion of the epiphysal line takes place, giving rise to apparent enlargement of the medial condyle of the femur, the line of the epiphysis becoming oblique, with a direction downward and medialward, instead of at right angles to the axis of the bone. If the deformity be marked, an osteotomy of the femur is required to correct it.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practised in cases of disorganization of the knee from other causes. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed by a horseshoe-shaped incision, starting from one femoral condyle, descending as low as the tuberosity of the tibia, and then carried upward to the other femoral condyle. The bone ends having been cleared, and in those cases where the operation is performed for tuberculous disease all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysal cartilage will be involved, with disastrous results as regards the growth of the limb. Afterward a thin slice, not more than 1.25 cm., should be removed from the upper end of the tibia. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge, rather than by a further section.

The bursæ about the knee-joint are sometimes the seat of enlargement. The bursa between the front of the patella and the skin is frequently affected in individuals who are in the habit of constantly kneeling, and the condition is then known as "housemaid's knee." The bursa beneath the Semimembranosus tendon also occasionally becomes enlarged, and forms a fluctuating swelling at the back of the knee. During extension, the swelling is firm and tense; but during flexion it becomes soft, and, as the bursa often communicates with the synovial cavity of the joint, the fluid it contains can be made to disappear by pressure when the knee is flexed. Extension of septic processes within the joint is apt to occur along the tendon sheath of the Popliteus, and this may lead to deep-seated suppuration in the popliteal fossa, often associated with septic thrombosis of the popliteal vein; when this occurs amputation of the limb is necessary.

III. Articulations between the Tibia and Fibula.

The articulations between the tibia and fibula are effected by ligaments which connect the extremities and bodies of the bones. The ligaments may consequently

be subdivided into three sets: (1) those of the Tibiofibular articulation; (2) the interosseous membrane; (3) those of the Tibiofibular syndesmosis.

Tibiofibular Articulation (*articulatio tibiofibularis; superior tibiofibular articulation*).—This articulation is an arthrodial joint between the lateral condyle of the tibia and the head of the fibula. The contiguous surfaces of the bones present flat, oval facets covered with cartilage and connected together by an articular capsule and by anterior and posterior ligaments.

The Articular Capsule (*capsula articularis; capsular ligament*).—The articular capsule surrounds the articulation, being attached around the margins of the articular facets on the tibia and fibula; it is much thicker in front than behind.

The Anterior Ligament (*anterior superior ligament*).—The anterior ligament of the head of the fibula (Fig. 468) consists of two or three broad and flat bands, which pass obliquely upward from the front of the head of the fibula to the front of the lateral condyle of the tibia.

The Posterior Ligament (*posterior superior ligament*).—The posterior ligament of the head of the fibula (Fig. 469) is a single thick and broad band, which passes obliquely upward from the back of the head of the fibula to the back of the lateral condyle of the tibia. It is covered by the tendon of the Popliteus.

Synovial Membrane.—A synovial membrane lines the capsule; it is continuous with that of the knee-joint in occasional cases when the two joints communicate.

Interosseous Membrane (*membrana interossea cruris; middle tibiofibular ligament*).—An interosseous membrane extends between the interosseous crests of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres, which for the most part run downward and lateralward; some few fibres, however, pass in the opposite direction. It is broader above than below. Its upper margin does not quite reach the tibiofibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels to the front of the leg. In its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the interosseous ligament of the tibiofibular syndesmosis, and presents numerous perforations for the passage of small vessels. It is in relation, in *front*, with the Tibialis anterior, Extensor digitorum longus, Extensor hallucis proprius, Peroneus tertius, and the anterior tibial vessels and deep peroneal nerve; *behind*, with the Tibialis posterior and Flexor hallucis longus.

Tibiofibular Syndesmosis (*syndesmosis tibiofibularis; inferior tibiofibular articulation*).—This syndesmosis is formed by the rough, convex surface of the medial side of the lower end of the fibula, and a rough concave surface on the lateral side of the tibia. Below, to the extent of about 4 mm. these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments are: anterior, posterior, inferior transverse, and interosseous.

The Anterior Ligament (*ligamentum malleoli lateralis anterior; anterior inferior ligament*).—The anterior ligament of the lateral malleolus (Fig. 476) is a flat, triangular band of fibres, broader below than above, which extends obliquely downward and lateralward between the adjacent margins of the tibia and fibula, on the front aspect of the syndesmosis. It is in relation, in *front*, with the Peroneus tertius, the aponeurosis of the leg, and the integument; *behind*, with the interosseous ligament; and lies in contact with the cartilage covering the talus.

The Posterior Ligament (*ligamentum malleoli lateralis posterior; posterior inferior ligament*).—The posterior ligament of the lateral malleolus (Fig. 476), smaller than the preceding, is disposed in a similar manner on the posterior surface of the syndesmosis.

The Inferior Transverse Ligament.—The inferior transverse ligament lies in front of the posterior ligament, and is a strong, thick band, of yellowish fibres which passes transversely across the back of the joint, from the lateral malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the talus.

The Interosseous Ligament.—The interosseous ligament consists of numerous short, strong, fibrous bands, which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. It is continuous, above, with the interosseous membrane.

Synovial Membrane.—The synovial membrane associated with the small arthrodial part of this joint is continuous with that of the ankle-joint.

IV. Talocrural Articulation or Ankle-joint (*Articulatio Talocruralis; Tibiotarsal Articulation*).

The ankle-joint is a ginglymus, or hinge-joint. The structures entering into its formation are the lower end of the tibia and its malleolus, the malleolus of the fibula, and the transverse ligament, which together form a mortise for the reception of the upper convex surface of the talus and its medial and lateral facets. The bones are connected by the following ligaments:

The Articular Capsule.

The Deltoid.

The Anterior Talofibular.

The Posterior Talofibular.

The Calcaneofibular.

The Articular Capsule (*capsula articularis; capsular ligament*).—The articular capsule surrounds the joints, and is attached, *above*, to the borders of the articular surfaces of the tibia and malleoli; and *below*, to the talus around its upper articular surface.

FIG. 475.—Right talocrural intertarsal and tarsometatarsal articulations. Medial aspect.

The anterior part of the capsule (*anterior ligament*) (Fig. 475) is a broad, thin, membranous layer, attached, *above*, to the anterior margin of the lower end of

the tibia; *below*, to the talus, in front of its superior articular surface. It is in relation, in *front*, with the Extensor tendons of the toes, the tendons of the Tibialis anterior and Peroneus tertius, and the anterior tibial vessels and deep peroneal nerve.

The posterior part of the capsule (*posterior ligament*) is very thin, and consists principally of transverse fibres. It is attached, *above*, to the margin of the articular surface of the tibia, blending with the transverse ligament; *below*, to the talus behind its superior articular facet. Laterally, it is somewhat thickened, and is attached to the hollow on the medial surface of the lateral malleolus.

The Deltoid Ligament (*ligamentum deltoideum*; *internal lateral ligament*) (Fig. 475).—The deltoid ligament is a strong, flat, triangular band, attached, *above*, to the apex and anterior and posterior borders of the medial malleolus. It consists of two sets of fibres, superficial and deep. Of the superficial fibres the most anterior (*tibionavicular*) pass forward to be inserted into the tuberosity of the navicular bone, and immediately behind this they blend with the medial margin of the plantar calcaneonavicular ligament; the middle (*calcaneotibial*) descend almost perpendicularly to be inserted into the whole length of the sustentaculum tali of the calcaneus; the posterior fibres (*posterior talotibial*) pass backward and lateralward to be attached to the inner side of the talus, and to the prominent tubercle on its posterior surface, medial to the groove for the tendon of the Flexor hallucis longus. The deep fibres (*anterior talotibial*) are attached, *above*, to the tip of the medial malleolus, and, *below*, to the medial surface of the talus. The deltoid ligament is covered by the tendons of the Tibialis posterior and Flexor digitorum longus.

The anterior and posterior talofibular and the calcaneofibular ligaments were formerly described as the three fasciculi of the *external lateral ligament* of the ankle-joint.

FIG. 476.—Right talocrural, intertarsal and tarsometatarsal articulations. Lateral aspect.

The Anterior Talofibular Ligament (*ligamentum talofibulare anterius*) (Fig. 476).—The anterior talofibular ligament, the shortest of the three, passes from the anterior margin of the fibular malleolus, forward and medially, to the talus, in front of its lateral articular facet.

The Posterior Talofibular Ligament (*ligamentum talofibulare posterius*) (Fig. 476).—The posterior talofibular ligament, the strongest and most deeply seated, runs almost horizontally from the depression at the medial and back part of the fibular malleolus to a prominent tubercle on the posterior surface of the talus immediately lateral to the groove for the tendon of the Flexor hallucis longus.

The Calcaneofibular Ligament (*ligamentum calcaneofibulare*) (Fig. 476).—The calcaneofibular ligament, the longest of the three, is a narrow, rounded cord, running from the apex of the fibular malleolus downward and slightly backward to a tubercle on the lateral surface of the calcaneus. It is covered by the tendons of the Peronaei longus and brevis.

FIG. 477.—Capsule of left talocrural articulation (distended). Lateral aspect.

Synovial Membrane (Fig. 477).—The synovial membrane invests the deep surfaces of the ligaments, and sends a small process upward between the lower ends of the tibia and fibula.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in *front*, from the medial side, the Tibialis anterior, Extensor hallucis proprius, anterior tibial vessels, deep peroneal nerve, Extensor digitorum longus, and Peronaeus tertius; *behind*, from the medial side, the Tibialis posterior, Flexor digitorum longus, posterior tibial vessels, tibial nerve, Flexor hallucis longus; and, in the groove behind the fibular malleolus, the tendons of the Peronaei longus and brevis.

The **arteries** supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

The **nerves** are derived from the deep peroneal and tibial.

Movements.—When the body is in the erect position, the foot is at right angles to the leg. The movements of the joint are those of dorsiflexion and extension; dorsiflexion consists in the approximation of the dorsum of the foot to the front of the leg, while in extension the heel is drawn up and the toes pointed downward. The malleoli tightly embrace the talus in all positions of the joint, so that any slight degree of side-to-side movement which may exist is simply due to stretching of the ligaments of the talofibular syndesmosis, and slight bending of the body of the fibula. The superior articular surface of the talus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight outward rotatory movement of the lower end of the fibula and a stretching of the ligaments of the syndesmosis; this lateral movement is facilitated by a slight gliding at the tibiofibular articulation, and possibly also by the bending of the body of the fibula. Of the ligaments, the deltoid is of very great power—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the calcaneofibular ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior talofibular ligament assists the calcaneofibular in

resisting the displacement of the foot backward, and deepens the cavity for the reception of the talus. The anterior talofibular is a security against the displacement of the foot forward, and limits extension of the joint.

The movements of inversion and eversion of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, etc., are mainly effected in the tarsal joints; the joint which enjoys the greatest amount of motion being that between the talus and calcaneus behind and the navicular and cuboid in front. This is often called the **transverse tarsal joint**, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the foot upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posterior, Peronaei longus and brevis, Flexor digitorum longus, and Flexor hallucis longus; *dorsiflexion*, by the Tibialis anterior, Peronaeus tertius, Extensor digitorum longus, and Extensor hallucis proprius.¹

Applied Anatomy.—As the ankle-joint is a very strong and powerful articulation, displacement of the talus from the tibiofibular mortise is a rare accident, and great force is required to produce it. Nevertheless, dislocation does occasionally occur, either antero-posteriorly or to one or other side. In the latter, which is the more common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontal direction, such as usually occurs in dislocations of ginglymoid joints, but the talus undergoes a partial rotation around an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upward, is inclined more or less medialward or lateralward according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the Tibialis anterior and the deltoid ligament on the medial side, and between the Peronaeus tertius and the anterior talofibular ligament laterally. In addition to this, bulging often occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo calcaneus. A large proportion of so-called "sprains" of the ankle have been proved by x-ray examination to be some variety of fracture about the malleoli, with or without displacement.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is liable to a recurrence of the injury; or the synovitis may be tuberculous in its origin, the disease usually beginning in the talus and extending to the joint, though it may commence in the synovial membrane, the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed, since the foot after excision is often of very little use; far less useful, in fact, than it is after Syme's amputation, which is, therefore, a preferable operation in these cases. Further, disease of the ankle-joint is frequently associated with disease of the tarsal bones.

V. Intertarsal Articulations (*Articulationes Intertarseae*; *Articulations of the Tarsus*).

Talocalcaneal Articulation (*articulatio talocalcanea*; *articulation of the calcaneus and astragalus*; *calcaneo-astragaloid articulation*).—The articulations between the calcaneus and talus are two in number—anterior and posterior. Of these, the anterior forms part of the talocalcaneonavicular joint, and will be described with that articulation. The posterior or talocalcaneal articulation is formed between the posterior calcaneal facet on the inferior surface of the talus, and the posterior facet on the superior surface of the calcaneus. It is an arthrodial joint, and the two bones are connected by an articular capsule and by anterior, posterior, lateral, medial, and interosseous talocalcaneal ligaments.

The Articular Capsule (*capsula articularis*).—The articular capsule envelops the joint, and consists for the most part of short fibres, which are split up into distinct slips; between these there is only a weak fibrous investment.

The Anterior Talocalcaneal Ligament (*ligamentum talocalcaneum anterius*; *anterior calcaneo-astragaloid ligament*) (Figs. 477, 480).—The anterior talocalcaneal ligament extends from the front and lateral surface of the neck of the talus to the superior surface of the calcaneus. It forms the posterior boundary of the

¹ The student must bear in mind that the Extensor digitorum longus and Extensor hallucis proprius are *extensors* of the toes, but *flexors* of the ankle; and that the Flexor digitorum longus and Flexor hallucis longus are *flexors* of the toes, but *extensors* of the ankle.

talocalcaneonavicular joint, and is sometimes described as the **anterior interosseous ligament**.

The Posterior Talocalcaneal Ligament (*ligamentum talocalcaneum posterius; posterior calcaneo-astragaloid ligament*) (Fig. 475).—The posterior talocalcaneal ligament connects the lateral tubercle of the talus with the upper and medial part of the calcaneus; it is a short band, and its fibres radiate from their narrow attachment to the talus.

The Lateral Talocalcaneal Ligament (*ligamentum talocalcaneum laterale; external calcaneo-astragaloid ligament*) (Figs. 477, 480).—The lateral talocalcaneal ligament is a short, strong fasciculus, passing from the lateral surface of the talus, immediately beneath its fibular facet to the lateral surface of the calcaneus. It is placed in front of, but on a deeper plane than, the calcaneofibular ligament, with the fibres of which it is parallel.

The Medial Talocalcaneal Ligament (*ligamentum talocalcaneum mediale; internal calcaneo-astragaloid ligament*).—The medial talocalcaneal ligament connects the medial tubercle of the back of the talus with the back of the sustentaculum tali. Its fibres blend with those of the plantar calcaneonavicular ligament.

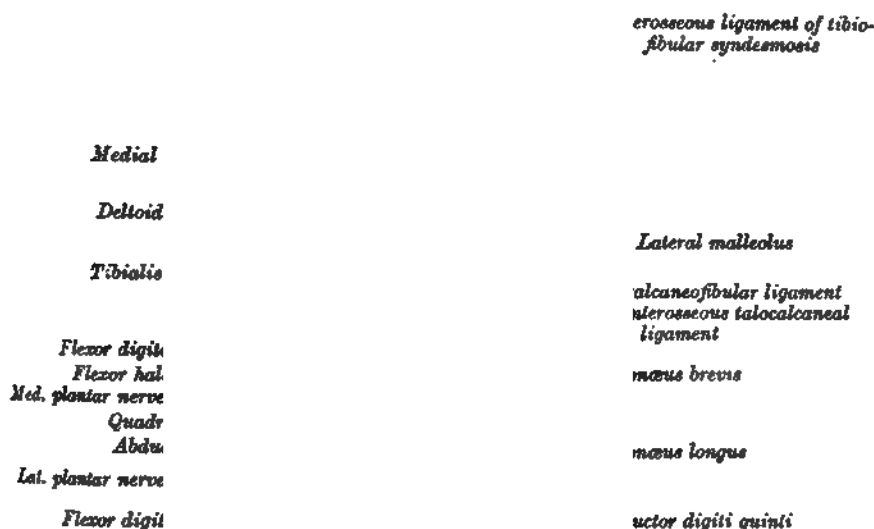

FIG. 478.—Coronal section through right talocrural and talocalcaneal joints.

The Interosseous Talocalcaneal Ligament (*ligamentum talocalcaneum interosseum*) (Figs. 478, 480).—The interosseous talocalcaneal ligament forms the chief bond of union between the bones. It is, in fact, a portion of the united capsules of the talocalcaneonavicular and the talocalcaneal joints, and consists of two partially united layers of fibres, one belonging to the former and the other to the latter joint. It is attached, *above*, to the groove between the articular facets of the under surface of the talus; *below*, to a corresponding depression on the upper surface of the calcaneus. It is very thick and strong, being at least 2.5 cm. in breadth from side to side, and serves to bind the calcaneus and talus firmly together.

Synovial Membrane (Fig. 481).—The synovial membrane lines the capsule of the joint, and is distinct from the other synovial membranes of the tarsus.

Movements.—The movements permitted between the talus and calcaneus are limited to gliding of the one bone on the other backward and forward and from side to side.

Talocalcaneonavicular Articulation (*articulatio talocalcaneonavicularis*).—This articulation is an arthrodial joint: the rounded head of the talus being received into the concavity formed by the posterior surface of the navicular, the anterior articular surface of the calcaneus, and the upper surface of the plantar calcaneonavicular ligament. There are two ligaments in this joint: the articular capsule and the dorsal talonavicular.

The Articular Capsule (*capsula articularis*).—The articular capsule is imperfectly developed except posteriorly, where it is considerably thickened and forms, with a part of the capsule of the talocalcaneal joint, the strong interosseous ligament which fills in the canal formed by the opposing grooves on the calcaneus and talus, as above mentioned.

The Dorsal Talonavicular Ligament (*ligamentum talonaviculare dorsale; superior astragalonavicular ligament*) (Fig. 475).—This ligament is a broad, thin band, which connects the neck of the talus to the dorsal surface of the navicular bone; it is covered by the Extensor tendons. The plantar calcaneonavicular supplies the place of a plantar ligament for this joint.

Synovial Membrane.—The synovial membrane lines all parts of the capsule of the joint.

Movements.—This articulation permits of a considerable range of gliding movements; its feeble construction allows occasionally of dislocation of the other bones of the tarsus from the talus.

Calcaneocuboid Articulation (*articulatio calcaneocuboida; articulation of the calcaneus with the cuboid*).—The ligaments connecting the calcaneus with the cuboid are five in number, viz., the articular capsule, the dorsal calcaneocuboid, part of the bifurcated, the long plantar, and the plantar calcaneocuboid.

The Articular Capsule (*capsula articularis*).—The articular capsule is an imperfectly developed investment, containing certain strengthened bands, which form the other ligaments of the joint.

The Dorsal Calcaneocuboid Ligament (*ligamentum calcaneocuboidum dorsale; superior calcaneocuboid ligament*) (Fig. 476).—The dorsal calcaneocuboid ligament is a thin but broad fasciculus, which passes between the contiguous surfaces of the calcaneus and cuboid, on the dorsal surface of the joint.

The Bifurcated Ligament (*ligamentum bifurcatum; internal calcaneocuboid; interosseous ligament*) (Fig. 476, 480).—The bifurcated ligament is a strong band, attached behind to the deep hollow on the upper surface of the calcaneus and dividing in front in a Y-shaped manner into a calcaneocuboid and a calcaneonavicular part. The calcaneocuboid part is fixed to the medial side of the cuboid and forms one of the principal bonds between the first and second rows of the tarsal bones. The calcaneonavicular part is attached to the lateral side of the navicular.

The Long Plantar Ligament (*ligamentum plantare longum; long calcaneocuboid ligament; superficial long plantar ligament*) (Fig. 479).—The long plantar ligament is the longest of all the ligaments of the tarsus: it is attached behind to the plantar surface of the calcaneus in front of the tuberosity, and in front to the tuberosity on the plantar surface of the cuboid bone, the more superficial fibres being continued forward to the bases of the second, third, and fourth metatarsal bones. This ligament converts the groove on the plantar surface of the cuboid into a canal for the tendon of the Peroneus longus.

The Plantar Calcaneocuboid Ligament (*ligamentum calcaneocuboidum plantare; short calcaneocuboid ligament; short plantar ligament*) (Fig. 479).—The plantar calcaneocuboid ligament lies nearer to the bones than the preceding, from which it is separated by a little areolar tissue. It is a short but wide band of great strength, and extends from the tubercle and the depression in front of it, on the forepart

of the plantar surface of the calcaneus, to the plantar surface of the cuboid behind the peroneal groove.

Synovial Membrane.—The synovial membrane lines the inner surface of the capsule and is distinct from that of the other tarsal articulations (Fig. 481).

Movements.—The movements permitted between the calcaneus and cuboid are limited to slight gliding movements of the bones upon each other.

The *transverse tarsal joint* is formed by the articulation of the calcaneus with the cuboid, and the articulation of the talus with the navicular. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the foot may be slightly flexed or extended, the sole being at the same time carried medially (inverted) or laterally (everted).

The Ligaments Connecting the Calcaneus and Navicular.—Though the calcaneus and navicular do not directly articulate, they are connected by two ligaments: the calcaneonavicular part of the bifurcated, and the plantar calcaneonavicular.

The calcaneonavicular part of the bifurcated ligament is described on page 454.

The Plantar Calcaneonavicular Ligament (*ligamentum calcaneonaviculare plantare; inferior or internal calcaneonavicular ligament; calcaneonavicular ligament*) (Fig. 480).—The plantar calcaneonavicular ligament is a broad and thick band of fibres, which connects the anterior margin of the sustentaculum tali of the calca-

FIG. 479.—Ligaments of plantar surface of the right foot.

FIG. 480.—Talocalcaneal and talocalcaneonavicular articulations exposed from above by removing the talus.

neus to the plantar surface of the navicular. This ligament not only serves to connect the calcaneus and navicular, but supports the head of the talus, forming part of the articular cavity in which it is received. The dorsal surface of the ligament presents a fibrocartilaginous facet, lined by the synovial membrane, and upon this a portion of the head of the talus rests. Its plantar surface is supported by the tendon of the Tibialis posterior; its medial border is blended with the forepart of the deltoid ligament of the ankle-joint.

Applied Anatomy.—The plantar calcaneonavicular ligament, by supporting the head of the talus, is principally concerned in maintaining the arch of the foot. When it yields, the head of the talus is pressed downward, medialward, and forward by the weight of the body, and the foot becomes flattened, expanded, and turned lateralward, and exhibits the condition known as *flat-foot*. This ligament contains a considerable amount of elastic fibres, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the "spring" ligament. It is supported, on its plantar surface, by the tendon of the Tibialis posterior, which spreads out at its insertion into a number of fasciculi, to be attached to most of the tarsal and metatarsal bones. This prevents undue stretching of the ligament, and is a protection against the occurrence of flat-foot; hence muscular weakness is, in most cases, the primary cause of the deformity.

Cuneonavicular Articulation (*articulatio cuneonavicularis; articulation of the navicular with the cuneiform bones*).—The navicular is connected to the three cuneiform bones by dorsal and plantar ligaments.

The Dorsal Ligaments (*ligamenta navicularicuneiformia dorsalia*).—The dorsal ligaments are three small bundles, one attached to each of the cuneiform bones. The bundle connecting the navicular with the first cuneiform is continuous around the medial side of the articulation with the plantar ligament which unites these two bones.

The Plantar Ligaments (*ligamenta navicularicuneiformia plantaria*).—The plantar ligaments have a similar arrangement to the dorsal, and are strengthened by slips from the tendon of the Tibialis posterior.

Metatarsals.

FIG. 481.—Oblique section of left intertarsal and tarsometatarsal articulations, showing the synovial cavities

Synovial Membrane.—The synovial membrane of these joints is part of the great tarsal synovial membrane (Fig. 481).

Movements.—Mere gliding movements are permitted between the navicular and cuneiform bones.

Cuboideonavicular Articulation.—The navicular bone is connected with the cuboid by dorsal, plantar, and interosseous ligaments.

The Dorsal Ligament (*ligamentum cuboideonaviculare dorsale*).—The dorsal ligament extends obliquely forward and lateralward from the navicular to the cuboid bone.

The Plantar Ligament (*ligamentum cuboideonaviculare plantare*).—The plantar ligament passes nearly transversely between these two bones.

The Interosseous Ligament.—The interosseous ligament consists of strong transverse fibres, and connects the rough non-articular portions of the adjacent surfaces of the two bones.

Synovial Membrane.—The synovial membrane of this joint is part of the great tarsal synovial membrane (Fig. 481).

Movements.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

Intercuneiform and Cuneocuboid Articulations.—The three cuneiform bones and the cuboid are connected together by dorsal, plantar, and interosseous ligaments.

The Dorsal Ligaments (*ligamenta intercuneiformia dorsalia*).—The dorsal ligaments consist of three transverse bands: one connects the first with the second cuneiform, another the second with the third cuneiform, and another the third cuneiform with the cuboid.

The Plantar Ligaments (*ligamenta intercuneiformia plantaria*).—The plantar ligaments have a similar arrangement to the dorsal, and are strengthened by slips from the tendon of the Tibialis posterior.

The Interosseous Ligaments (*ligamenta intercuneiformia interossea*).—The interosseous ligaments consist of strong transverse fibres which pass between the rough non-articular portions of the adjacent surfaces of the bones.

Synovial Membrane.—The synovial membrane of these joints is part of the great tarsal synovial membrane (Fig. 481).

Movements.—The movements permitted between these bones are limited to a slight gliding upon each other.

Applied Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur. When this takes place, it is most commonly in connection with the talus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the bone remaining *in situ* in the tibiofibular mortise. This constitutes what is known as the *subtalar* dislocation. Or, again, the talus may be dislocated from all its connections—from the tibia and fibula above, the calcaneus below, and the navicular in front—and may even undergo a rotation, on either a vertical or a horizontal axis. In the former case the long axis of the bone is directed across the joint, so that the head faces the articular surface on one or other malleolus; in the latter, the collateral surfaces are directed upward and downward, so that the superior surface faces to one or the other side. Reduction in these cases is often very difficult or impossible, and the displaced talus may require removal by open operation. Dislocation may also occur at the transverse tarsal joint, the anterior tarsal bones being luxated from the talus and calcaneus. The other tarsal bones are occasionally, though rarely, dislocated from their connections.

VI. Tarsometatarsal Articulations (*Articulationes Tarsometatarsee*).

These are arthrodial joints. The bones entering into their formation are the first, second, and third cuneiforms, and the cuboid, which articulate with the bases of the metatarsal bones. The first metatarsal bone articulates with the first cuneiform; the second is deeply wedged in between the first and third cuneiforms articulating by its base with the second cuneiform; the third articulates with the third cuneiform; the fourth, with the cuboid and third cuneiform; and the fifth, with the cuboid. The bones are connected by dorsal, plantar, and interosseous ligaments.

The Dorsal Ligaments (*ligamenta tarsometatarsee dorsalia*).—The dorsal ligaments are strong, flat bands. The first metatarsal is joined to the first cuneiform by a broad, thin band; the second has three, one from each cuneiform bone; the third

has one from the third cuneiform; the fourth has one from the third cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The Plantar Ligaments (*ligamenta tarsometatarsea plantaria*).—The plantar ligaments consist of longitudinal and oblique bands, disposed with less regularity than the dorsal ligaments. Those for the first and second metatarsals are the strongest; the second and third metatarsals are joined by oblique bands to the first cuneiform; the fourth and fifth metatarsals are connected by a few fibres to the cuboid.

The Interosseous Ligaments (*ligamenta cuneometatarsea interossia*).—The interosseous ligaments are three in number. The first is the strongest, and passes from the lateral surface of the first cuneiform to the adjacent angle of the second metatarsal. The second connects the third cuneiform with the adjacent angle of the second metatarsal. The third connects the lateral angle of the third cuneiform with the adjacent side of the base of the third metatarsal.

Synovial Membrane (Fig. 481).—The synovial membrane between the first cuneiform and the first metatarsal forms a distinct sac. The synovial membrane between the second and third cuneiforms behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forward from it, one between the adjacent sides of the second and third, and another between those of the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones forms a distinct sac. From it a prolongation is sent forward between the fourth and fifth metatarsal bones.

Movements.—The movements permitted between the tarsal and metatarsal bones are limited to slight gliding of the bones upon each other.

Nerve Supply.—The intertarsal and tarsometatarsal joints are supplied by the deep peroneal nerve.

VII. Intermetatarsal Articulations (*Articulationes Intermetatarsee*).

The base of the first metatarsal is not connected with that of the second by any ligaments; in this respect the great toe resembles the thumb.

The bases of the other four metatarsals are connected by the dorsal, plantar, and interosseous ligaments.

The Dorsal Ligaments (*ligamenta basium [oss. metatars.] dorsalia*) pass transversely between the dorsal surfaces of the bases of the adjacent metatarsal bones.

The Plantar Ligaments (*ligamenta basium [oss. metatars.] plantaria*).—The plantar ligaments have a similar arrangement to the dorsal.

The Interosseous Ligaments (*ligamenta basium [oss. metatars.] interossea*).—The interosseous ligaments consist of strong transverse fibres which connect the rough non-articular portions of the adjacent surfaces.

Synovial Membranes (Fig. 481).—The synovial membranes between the second and third, and the third and fourth metatarsal bones are part of the great tarsal synovial membrane; that between the fourth and fifth is a prolongation of the synovial membrane of the cuboideometatarsal joint.

Movements.—The movement permitted between the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

The heads of all the metatarsal bones are connected together by the transverse metatarsal ligament.

The Transverse Metatarsal Ligament.—The transverse metatarsal ligament is a narrow band which runs across and connects together the heads of all the metatarsal bones; it is blended anteriorly with the plantar (glenoid) ligaments of the metatarsophalangeal articulations. Its plantar surface is concave where the Flexor tendons run below it; above it the tendons of the Interossei pass to their insertions. It differs from the transverse metacarpal ligament in that it connects the metatarsal to the others.

The Synovial Membranes in the Tarsal and Tarsometatarsal Joints (Fig. 481).—The synovial membranes found in the articulations of the tarsus and metatarsus are six in number: one for

the talocalcaneal articulation; a second for the talocalcaneonavicular articulation; a third for the calcaneocuboid articulation; and a fourth for the cuneonavicular, intercuneiform, and cuneocuboid articulations, the articulations of the second and third cuneiforms with the bases of the second and third metatarsal bones, and the adjacent surfaces of the bases of the second, third, and fourth metatarsal bones; a fifth for the first cuneiform with the metatarsal bone of the great toe; and a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial cavity is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

VIII. Metatarsophalangeal Articulations (*Articulationes Metatarsophalangeae*).

The metatarsophalangeal articulations are of the condyloid kind, formed by the reception of the rounded heads of the metatarsal bones in shallow cavities on the ends of the first phalanges.

The ligaments are the plantar and two collateral.

The Plantar Ligaments (*ligamenta accessoria plantaria; glenoid ligaments of Cruveilhier*).—The plantar ligaments are thick, dense, fibrous structures. They are placed on the plantar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected; they are loosely united to the metatarsal bones, but very firmly to the bases of the first phalanges. Their plantar surfaces are intimately blended with the transverse metatarsal ligament, and grooved for the passage of the Flexor tendons, the sheaths surrounding which are connected to the sides of the grooves. Their deep surfaces form part of the articular facets for the heads of the metatarsal bones, and are lined by synovial membrane.

The Collateral Ligaments (*ligamenta collateralia; lateral ligaments*).—The collateral ligaments are strong, rounded cords, placed one on either side of each joint, and attached, by one end, to the posterior tubercle on the side of the head of the metatarsal bone, and, by the other, to the contiguous extremity of the phalanx.

The place of **dorsal ligaments** is supplied by the Extensor tendons on the dorsal surfaces of the joints.

Movements.—The movements permitted in the metatarsophalangeal articulations are flexion, extension, abduction, and adduction.

IX. Articulations of the Digits (*Articulationes Digitorum Pedis; Articulations of the Phalanges*).

The interphalangeal articulations are ginglymoid joints, and each has a plantar and two collateral ligaments.

The arrangement of these ligaments is similar to that in the metatarsophalangeal articulations: the Extensor tendons supply the places of dorsal ligaments.

Movements.—The only movements permitted in the joints of the digits are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The amount of flexion is very considerable, but extension is limited by the plantar and collateral ligaments.

Applied Anatomy.—Gout peculiarly affects the metatarsophalangeal joint of the big toe, beginning with the deposit of sodium and calcium urates in the articular cartilages, and slow necrosis of the surrounding tissue. Later the circumarticular fibrous tissue becomes the seat of these gouty deposits, and considerable thickening and deformity may result. The other chief joint affections, such as rheumatism, gonorrhoeal arthritis, tuberculosis, or syphilis, seldom attack the big toe-joint; but septic arthritis associated with perforating ulcer of the foot is not uncommon.

Arches of the Foot.

In order to allow it to support the weight of the body in the erect posture with the least expenditure of material, the foot is constructed of a series of arches formed by the tarsal and metatarsal bones, and strengthened by the ligaments and tendons of the foot.

The main arches are the **antero-posterior arches**, which may, for descriptive purposes, be regarded as divisible into two types—a medial and a lateral. The **medial arch** (see Fig. 417, page 376) is made up by the calcaneus, the talus, the navicular, the three cuneiforms, and the first, second, and third metatarsals. Its summit is at the superior articular surface of the talus, and its two extremities or piers, on which it rests in standing, are the tuberosity on the plantar surface of the calcaneus posteriorly and the heads of the first, second, and third metatarsal bones anteriorly. The chief characteristic of this arch is its elasticity, due to its height and to the number of small joints between its component parts. Its weakest part, *i. e.*, the part most liable to yield from overpressure, is the joint between the talus and navicular, but this portion is braced by the plantar calcaneonavicular ligament, which is elastic and is thus able to quickly restore the arch to its pristine condition when the disturbing force is removed. The ligament is strengthened medially by blending with the deltoid ligament of the ankle-joint, and is supported inferiorly by the tendon of the Tibialis posterior, which is spread out in a fan-shaped insertion and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it. The arch is further supported by the plantar aponeurosis, by the small muscles in the sole of the foot, by the tendons of the Tibialis anterior and posterior and Peroneus longus, and by the ligaments of all the articulations involved. The **lateral arch** (see Fig. 418, page 376) is composed of the calcaneus, the cuboid, and the fourth and fifth metatarsals. Its summit is at the talocalcaneal articulation, and its chief joint is the calcaneocuboid, which possesses a special mechanism for locking, and allows only a limited movement. The most marked features of this arch are its solidity and its slight elevation; two strong ligaments, the long plantar and the plantar calcaneocuboid, together with the Extensor tendons and the short muscles of the little toe, preserve its integrity.

While these medial and lateral arches may be readily demonstrated as the component antero-posterior arches of the foot, yet the **fundamental longitudinal arch** is contributed to by both, and consists of the calcaneus, cuboid, third cuneiform, and third metatarsal: all the other bones of the foot may be removed without destroying this arch.

In addition to the longitudinal arches the foot presents a series of **transverse arches**. At the posterior part of the metatarsus and the anterior part of the tarsus the arches are complete, but in the middle of the tarsus they present more the characters of half-domes the concavities of which are directed downward and medialward, so that when the medial borders of the feet are placed in apposition a complete tarsal dome is formed. The transverse arches are strengthened by the interosseous, plantar, and dorsal ligaments, by the short muscles of the first and fifth toes (especially the transverse head of the Adductor hallucis), and by the Peroneus longus, whose tendon stretches across between the piers of the arches.

MYOLOGY.¹

THE Muscles are connected with the bones, cartilages, ligaments, and skin, either directly, or through the intervention of fibrous structures called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres end in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with its skin, they lie as a flattened layer beneath it, and are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face.

The muscles vary extremely in their form. In the limbs, they are of considerable length, especially the more superficial ones; they surround the bones, and constitute an important protection to the various joints. In the trunk, they are broad, flattened, and expanded, and assist in forming the walls of the trunk cavities. Hence the reason of the terms, **long**, **broad**, **short**, etc., used in the description of a muscle.

There is considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some muscles the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyreohyoideus. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at either end; in their actions, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles—*e. g.*, the Temporalis. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of the line of insertion; such is the case in the Pectineus. Thirdly, in some muscles (*e. g.*, the Peronei) the fibres are oblique and converge, like the plumes of a quill pen, to one side of a tendon which runs the entire length of the muscle; such muscles are termed **unipennate**. A modification of this condition is found where oblique fibres converge to both sides of a central tendon; these are called **bipennate**, and an example is afforded in the Rectus femoris. Finally, there are muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincters. The arrangement of the fibres is of considerable importance in respect to the relative strength and range of movement of the muscle. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

The names applied to the various muscles have been derived: (1) from their situation, as the Tibialis, Radialis, Ulnaris, Peronaeus; (2) from their direction, as the Rectus abdominis, Obliqui capitis, Transversus abdominis; (3) from their uses, as Flexors, Extensors, Abductors, etc.; (4) from their shape, as the Deltoideus,

¹ The muscles and fasciae are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciae separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciae, the special descriptions being given in connection with the different regions.

Rhomboideus; (5) from the number of their divisions, as the Biceps and Triceps; (6) from their points of attachment, as the Sternocleidomastoideus, Sternohyoideus, Sternothyreoideus.

In the description of a muscle, the term *origin* is meant to imply its more fixed or central attachment; and the term *insertion* the movable point on which the force of the muscle is applied; but the origin is absolutely fixed in only a small number of muscles, such as those of the face which are attached by one extremity to immovable bones, and by the other to the movable integument; in the greater number, the muscle can be made to act from either extremity.

In the dissection of the muscles, attention should be directed to the exact *origin*, *insertion*, and *actions* of each, and to its more important *relations* with surrounding parts. While accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their actions, it is not to be regarded as conclusive. The action of the muscle deduced from its attachments, or even by pulling on it in the dead subject, is not necessarily its action in the living. By pulling, for example, on the Brachioradialis in the cadaver the hand may be slightly supinated when in the prone position and slightly pronated when in the supine position, but there is no evidence that these actions are performed by the muscle during life. It is impossible for an individual to throw into action any one muscle; in other words, movements, not muscles, are represented in the central nervous system. To carry out a movement a definite combination of muscles is called into play, and the individual has no power either to leave out a muscle from this combination or to add one to it. One (or more) muscle of the combination is the chief moving force; when this muscle passes over more than one joint other muscles (*synergic muscles*) come into play to inhibit the movements not required; a third set of muscles (*fixation muscles*) fix the limb—*i. e.*, in the case of the limb-movements—and also prevent disturbances of the equilibrium of the body generally. As an example, the movement of the closing of the fist may be considered: (1) the prime movers are the Flexores digitorum, Flexor pollicis longus, and the small muscles of the thumb; (2) the synergic muscles are the Extensores carpi, which prevent flexion of the wrist; while (3) the fixation muscles are the Biceps and Triceps brachii, which steady the elbow and shoulder. A further point which must be borne in mind in considering the actions of muscles is that in certain positions a movement can be effected by gravity, and in such a case the muscles acting are the antagonists of those which might be supposed to be in action. Thus in flexing the trunk when no resistance is interposed the Sacrospinales contract to regulate the action of gravity, and the Recti abdominis are relaxed.¹

By a consideration of the action of the muscles, the surgeon is able to explain the causes of displacement in various forms of fracture, and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger bloodvessels, and the surface markings they produce, should be remembered, as they form useful guides in the application of ligatures to those vessels.

The minute anatomy of muscular tissue is described on pages 64 to 69.

Applied Anatomy.—Degeneration of muscular tissue is important clinically, and is met with in two main conditions. In one, the degeneration is myopathic, or primary in the muscles themselves; in the other it is neuropathic, or secondary to some lesion of the nervous system—a hemorrhage into the brain, for example, or injury or inflammation of some part of the medulla spinalis or peripheral nerves. In either case more or less paralysis and atrophy of the affected muscles result. When the degeneration begins primarily in the muscles, however, it often happens that though the muscle fibres waste away, their place is taken by fibrous and fatty tissue to such an extent that the affected muscles increase in volume, and actually appear to hypertrophy.

¹ Consult in this connection the Croonian Lectures (1933) on "Muscular Movements and Their Representation in the Central Nervous System," by Charles E. Beevor, M.D.

Ossification of muscular tissue as a result of repeated strain or injury is not infrequent. It is oftenest found about the tendon of the Adductor longus and Vastus medialis in horsemen, or in the Pectoralis major and Deltoideus of soldiers. It may take the form of exostoses firmly fixed to the bone—e. g., “rider’s bone” on the femur—or of layers or spicules of bone lying in the muscles or their fasciæ and tendons. Busse states that these bony deposits are preceded by a hemorrhagic myositis due to injury, the effused blood organizing and being finally converted into bone. In the rarer disease, progressive myositis ossificans, there is an unexplained tendency for practically any of the voluntary muscles to become converted into solid and brittle bony masses which are completely rigid.

TENDONS, APONEUROSSES, AND FASCIÆ.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with bloodvessels, the smaller tendons presenting in their interior no trace of them. Nerves supplying tendons have special modifications of their terminal fibres, named organs of Golgi.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly white color, iridescent, glistening, and similar in structure to the tendons. They are only sparingly supplied with bloodvessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles, and, on the other hand, with the movable structures, as the bones, cartilages ligaments, and fibrous membranes (for instance, the sclera). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous. But where the muscular fibres join the tendon or aponeurosis at an oblique angle, they end, according to Kölliker, in rounded extremities which are received into corresponding depressions on the surface of the latter, the connective tissue between the muscular fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

The **fasciæ** are fibroareolar or aponeurotic laminæ, of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. During the process of development many of the cells of the mesoderm are differentiated into bones, muscles, vessels, etc.; the cells of the mesoderm which are not so utilized form an investment for these structures and are differentiated into the true skin and the fasciæ of the body. They have been subdivided, from the situations in which they occur, into superficial and deep.

The **superficial fascia** is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep fascia, and consists of fibroareolar tissue, containing in its meshes pellicles of fat in varying quantity. It varies in thickness in different parts of the body; in the groin it is so thick that it may be subdivided into several laminæ. Beneath the fatty layer there is generally another layer of superficial fascia, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as the superficial epigastric vessels in the abdominal region, the superficial veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymph glands. Certain cutaneous muscles also are situated in the superficial fascia, as the Platysma in the neck, and the Orbicularis oculi around the eyelids. This fascia is most distinct at the lower part of the abdomen, perineum, and extremities; it is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands, and soles of the feet, forming a fibro-fatty layer, which binds the integument firmly to the underlying structures.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft nidus for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolæ is a bad conductor of heat.

The **deep fascia** is a dense, inelastic, fibrous membrane, forming sheaths for the muscles, and in some cases affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It forms a strong investment which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciæ are thick in unprotected situations, as on the lateral side of a limb, and thinner on the medial side. The deep fasciæ assist the muscles in their actions, by the degree of tension and pressure they make upon their surfaces; and, in certain situations, where they are strengthened by the presence in them of degenerated muscular fibres which have become converted into fibrous sheets, the degree of tension and pressure is regulated by the associated muscles, as, for instance, by the *Tensor fasciæ latae* and *Glutæus maximus* in the thigh, by the *Biceps* in the upper and lower extremities, and *Palmaris longus* in the hand. In the limbs, the fasciæ not only invest the entire limb, but give off septa which separate the various muscles, and are attached to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

The Fasciæ and Muscles may be arranged, according to the general division of the body, into those of the **head and neck**; of the **trunk**; of the **upper extremity**; and of the **lower extremity**.

THE FASCIÆ AND MUSCLES OF THE HEAD.

I. THE MUSCLE OF THE SCALP.

Epicranius.

Dissection (Fig. 482).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin, commencing at the root of the nose in front,

section of scalp.

FIG. 482.—Dissection of the head, face, and neck.

and terminating behind at the occipital protuberance; make a second incision in a horizontal direction along the forehead and around the side of the head, from the anterior to the posterior

extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upward; this must be done with extreme care, removing the integument from the outer surface of the vessels and the nerves which lie immediately beneath the skin.

The Skin of the Scalp.—This is thicker than in any other part of the body. It is intimately adherent to the superficial fascia, which attaches it firmly to the underlying aponeurosis and muscle. Movements of the muscle move the skin. The hair follicles are very closely set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

Dilator naris a
Dilator naris p

FIG. 483.—Muscles of the head, face, and neck.

The **superficial fascia** in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the Epicranius and its tendinous aponeurosis; it is continuous, behind, with the superficial fascia at the back of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

The **Epicranius** (*Occipitofrontalis*) (Fig. 483) is a broad, musculofibrous layer, which covers the whole of one side of the vertex of the skull, from the occipital

bone to the eyebrow. It consists of two parts, the Occipitalis and the Frontalis, connected by an intervening tendinous aponeurosis, the *galea aponeurotica*.

The **Occipitalis**, thin and quadrilateral in form, *arises* by tendinous fibres from the lateral two-thirds of the superior nuchal line of the occipital bone, and from the mastoid part of the temporal. It ends in the *galea aponeurotica*.

The **Frontalis** is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader than the Occipitalis and its fibres are longer and paler in color. It has no bony attachments. Its medial fibres are continuous with those of the Procerus; its immediate fibres blend with the Corrugator and Orbicularis oculi; and its lateral fibres are also blended with the latter muscle over the zygomatic process of the frontal bone. From these attachments the fibres are directed upward, and join the *galea aponeurotica* below the coronal suture. The medial margins of the Frontales are joined together for some distance above the root of the nose; but between the Occipitales there is a considerable, though variable, interval, occupied by the *galea aponeurotica*.

The *galea aponeurotica* (*epicranial aponeurosis*) covers the upper part of the cranium; behind, it is attached, in the interval between the Occipitales, to the external occipital protuberance and highest nuchal lines of the occipital bone; in front, it forms a short and narrow prolongation between the Frontales. On either side it gives origin to the Auriculares anterior and superior; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygomatic arch as a layer of laminated areolar tissue. It is closely connected to the integument by the firm, dense, fibro-fatty layer which forms the superficial fascia of the scalp: it is attached to the pericranium by loose cellular tissue, which allows the aponeurosis, carrying with it the integument to move through a considerable distance.

Nerves.—The Frontalis is supplied by the temporal branches of the facial nerve, and the Occipitalis by the posterior auricular branch of the same nerve.

Actions.—The Frontales raise the eyebrows and the skin over the root of the nose, and at the same time draw the scalp forward, throwing the integument of the forehead into transverse wrinkles. The Occipitales draw the scalp backward. By bringing alternately into action the Frontales and Occipitales the entire scalp may be moved forward and backward. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the Occipitales, thus giving to the face the expression of surprise; if the action be exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

A thin muscular slip, the **Transversus nuchae**, is present in a considerable proportion (25 per cent.) of cases; it *arises* from the external occipital protuberance or from the superior nuchal line, either superficial or deep to the Trapezii; it is frequently *inserted* with the Auricularis posterior, but may join the posterior edge of the Sternocleidomastoideus.

Applied Anatomy.—From an anatomical point of view, the scalp consists of five layers, viz., the skin, subcutaneous tissue, Epicranium and its aponeurosis, subaponeurotic connective tissue, and pericranium. But from a surgical standpoint it is better to regard the first three of these structures as a single layer, since they are all intimately fused together, and when torn off in an accident, or turned down as a flap in a surgical operation, remain firmly connected to each other. In consequence of the dense character of the subcutaneous tissue, the amount of swelling which occurs as the result of inflammation is slight; and the edges of a wound which does not involve the Epicranium or its aponeurosis do not gape. The bloodvessels, also, which lie in this tissue, when wounded, do not contract and retract freely; and therefore the hemorrhage from scalp wounds is often very considerable, but can always be arrested by pressure—a matter of great importance, as it is often very difficult or impossible to pick up with forceps a wounded vessel in the scalp.

The subaponeurotic connective tissue is, from a surgical point of view, of considerable importance. It is loose and lax, and is easily torn through; and hence, when the scalp is wounded, this is the tissue which is torn when the flap is separated from the parts beneath. The vessels are contained in the flap, and there is little risk of sloughing, unless the vitality of the part has been

actually destroyed by the injury. In consequence of the loose nature of the subaponeurotic tissue, any septic inflammation is apt to assume a very diffuse form and spread over the skull, and, unless relieved by timely incisions, may lead to serious complications. Owing to the attachments of the aponeurosis to the zygomatic arch and highest nuchal line, subaponeurotic effusions sag down in these situations, but do not extend beyond to the infratemporal fossa or into the neck; anteriorly, however, where there is no definite attachment to bone, the effusion will pass down over the nose, and into the eyelids. When making incisions into the scalp, care should be taken to avoid the course of the main arteries.

The skin of the scalp is abundantly supplied with sebaceous and sudoriparous glands. The former are sometimes the seat of cystic enlargement, constituting the so-called *sebaceous cysts* or *wens*.

II. THE MUSCLES OF THE EYELIDS.

The muscles of the eyelids are:

Levator palpebrae superioris. Orbicularis oculi. Corrugator.

Dissection (Fig. 482).—In order to expose the muscles of the face, continue the longitudinal incision made in the dissection of the Epicranius down the median line of the face to the tip of the nose, and from this point onward to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the mandible. Then make an incision in front of the external ear, from the angle of the mandible upward to join the transverse incision made in exposing the Epicranius. These incisions include a square-shaped flap, which should be removed in the direction marked in the figure, with care, as the muscles at some points are intimately adherent to the integument.

The Levator palpebrae superioris is described with the Anatomy of the Eye.

FIG. 484.—Left orbicularis oculi, seen from behind.

The **Orbicularis oculi** (*Orbicularis palpebrarum*) (Fig. 484) arises from the nasal part of the frontal bone, from the frontal process of the maxilla in front of the lacrimal groove, and from the anterior surface and borders of a short fibrous band,

the **medial palpebral ligament**. From this origin, the fibres are directed lateralward, forming a broad and thin layer, which occupies the eyelids or palpebrae, surrounds the circumference of the orbit, and spreads over the temple, and downward on the cheek. The **palpebral portion** of the muscle is thin and pale; it *arises* from the bifurcation of the medial palpebral ligament, forms a series of concentric curves, and is *inserted* into the lateral palpebral raphé. The **orbital portion** is thicker and of a reddish color; its fibres form a complete ellipse without interruption at the lateral palpebral commissure; the upper fibres of this portion blend with the Frontalis and Corrugator. The **lacrimal part** (*Tensor tarsi*) is a small, thin muscle, about 6 mm. in breadth and 12 mm. in length, situated behind the medial palpebral ligament and lacrimal sac (Fig. 484). It *arises* from the posterior crest and adjacent part of the orbital surface of the lacrimal bone, and passing behind the lacrimal sac, divides into two slips, upper and lower, which are *inserted* into the superior and inferior tarsi medial to the puncta lacrimalia; occasionally it is very indistinct.

The **medial palpebral ligament** (*tendo oculi*), about 4 mm. in length and 2 mm. in breadth, is attached to the frontal process of the maxilla in front of the lacrimal groove. Crossing the lacrimal sac, it divides into two parts, upper and lower, each attached to the medial end of the corresponding tarsus. As the ligament crosses the lacrimal sac, a strong aponeurotic lamina is given off from its posterior surface; this expands over the sac, and is attached to the posterior lacrimal crest.

The **lateral palpebral raphé** is a much weaker structure than the medial palpebral ligament. It is attached to the margin of the frontosphenoidal process of the zygomatic bone, and passes medialward to the lateral commissure of the eyelids, where it divides into two slips, which are attached to the margins of the respective tarsi.

The **Corrugator**¹ (*Corrugator supercilii*) is a small, narrow, pyramidal muscle, placed at the medial end of the eyebrow, beneath the Frontalis and Orbicularis oculi. It *arises* from the medial end of the superciliary arch; and its fibres pass upward and lateralward, between the palpebral and orbital portions of the Orbicularis oculi, and are *inserted* into the deep surface of the skin, above the middle of the orbital arch.

Nerves.—The Orbicularis oculi and Corrugator are supplied by the facial nerve.

Actions.—The Orbicularis oculi is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbital portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn toward the medial angle of the orbit, and the eyelids are firmly closed, as in photophobia. The skin thus drawn upon is thrown into folds, especially radiating from the lateral angle of the eyelids; these folds become permanent in old age, and form the so-called "crows' feet." The Levator palpebrae superioris is the direct antagonist of this muscle; it raises the upper eyelid and exposes the front of the bulb of the eye. Each time the eyelids are closed through the action of the Orbicularis, the medial palpebral ligament is tightened, the wall of the lacrimal sac is thus drawn lateralward and forward, so that a vacuum is made in it, and the tears are sucked along the lacrimal canals into it. The lacrimal part of the Orbicularis oculi draws the eyelids and the ends of the lacrimal canals medialward and compresses them against the surface of the globe of the eye, thus placing them in the most favorable situation for receiving the tears; it also compresses the lacrimal sac. The Corrugator draws the eyebrow downward and medialward, producing the vertical wrinkles of the forehead. It is the "frowning" muscle, and may be regarded as the principal muscle in the expression of suffering.

III. THE MUSCLES OF THE NOSE (Fig. 483).

The muscles of the nose comprise:

Procerus.
Nasalis.

Depressor septi.
Dilatator naris posterior.

Dilatator naris anterior.

¹ The corrugator is not recognized as a separate muscle in the Basle Nomenclature.

The **Procerus** (*Pyramidalis nasi*) is a small pyramidal slip arising by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the lateral nasal cartilage; it is *inserted* into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Frontalis.

The **Nasalis** (*Compressor naris*) consists of two parts, transverse and alar. The **transverse part** *arises* from the maxilla, above and lateral to the incisive fossa; its fibres proceed upward and medialward, expanding into a thin aponeurosis which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Procerus. The **alar part** is attached by one end to the greater alar cartilage, and by the other to the integument at the point of the nose.

The **Depressor septi** (*Depressor alae nasi*) *arises* from the incisive fossa of the maxilla; its fibres ascend to be *inserted* into the septum and back part of the ala of the nose. It lies between the mucous membrane and muscular structure of the lip.

The **Dilatator naris posterior** is placed partly beneath the Quadratus labii superioris. It *arises* from the margin of the nasal notch of the maxilla, and from the lesser alar cartilages, and is *inserted* into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a delicate fasciculus, passing from the greater alar cartilage to the integument near the margin of the nostril; it is situated in front of the preceding.

Nerves.—All the muscles of this group are supplied by the facial nerve.

Actions.—The Procerus draws down the medial angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The two Dilatores enlarge the aperture of the nares. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing, as well as in some emotions, such as anger, they contract strongly. The Depressor septi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downward, and thereby constricting the aperture of the nares. The Nasalis depresses the cartilaginous part of the nose and draws the ala toward the septum.

IV. THE MUSCLES OF THE MOUTH.

The muscles of the mouth are:

Quadratus labii superioris.
Caninus.
Zygomaticus.
Mentalis.

Quadratus labii inferioris.
Triangularis.
Buccinator.
Orbicularis oris.

Risorius.

Dissection.—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches and the integument carefully removed from the surface.

The **Quadratus labii superioris** is a broad sheet, the origin of which extends from the side of the nose to the zygomatic bone. Its medial fibres form the **angular head**, which *arises* by a pointed extremity from the upper part of the frontal process of the maxilla and passing obliquely downward and lateralward divides into two slips. One of these is *inserted* into the greater alar cartilage and skin of the nose; the other is prolonged into the lateral part of the upper lip, blending with the infraorbital head and with the Orbicularis oris. The intermediate portion or **infraorbital head** *arises* from the lower margin of the orbit immediately above the infraorbital foramen, some of its fibres being attached to the maxilla, others to the zygomatic bone. Its fibres converge, to be *inserted* into the muscular substance

of the upper lip between the angular head and the Caninus. The lateral fibres, forming the **zygomatic head**, *arise* from the malar surface of the zygomatic bone immediately behind the zygomaticomaxillary suture and pass downward and medialward to the upper lip.

The **Caninus** (*Levator anguli oris*) *arises* from the canine fossa, immediately below the infraorbital foramen; its fibres are *inserted* into the angle of the mouth, intermingling with those of the Zygomaticus, Triangularis, and Orbicularis oris.

The **Zygomaticus** (*Zygomaticus major*) *arises* from the zygomatic bone, in front of the zygomaticotemporal suture, and descending obliquely with a medial inclination, is *inserted* into the angle of the mouth, where it blends with the fibres of the Caninus, Orbicularis oris, and Triangularis.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Quadratus labii superioris is the proper elevator of the upper lip, carrying it at the same time a little forward. Its angular head acts as a dilator of the naris; the infraorbital and zygomatic heads assist in forming the nasolabial furrow, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. When the whole muscle is in action it gives to the countenance an expression of contempt and disdain. The Quadratus labii superioris raises the angle of the mouth and assists the Caninus in producing the nasolabial furrow. The zygomaticus draws the angle of the mouth backward and upward, as in laughing.

The **Mentalis** (*Levator menti*) is a small conical fasciculus, situated at the side of the frenulum of the lower lip. It *arises* from the incisive fossa of the mandible, and descends to be *inserted* into the integument of the chin.

The **Quadratus labii inferioris** (*Depressor labii inferioris*; *Quadratus menti*) is a small quadrilateral muscle. It *arises* from the oblique line of the mandible, between the symphysis and the mental foramen, and passes upward and medialward, to be *inserted* into the integument of the lower lip, its fibres blending with the Orbicularis oris, and with those of its fellow of the opposite side. At its origin it is continuous with the fibres of the Platysma. Much yellow fat is intermingled with the fibres of this muscle.

The **Triangularis** (*Depressor anguli oris*) *arises* from the oblique line of the mandible, whence its fibres converge, to be *inserted*, by a narrow fasciculus, into the angle of the mouth. At its origin it is continuous with the Platysma, and at its insertion with the Orbicularis oris and Risorius; some of its fibres are directly continuous with those of the Caninus, and others are occasionally found crossing from the muscle of one side to that of the other; these latter fibres constitute the **Transversus menti**.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Mentalis raises and protrudes the lower lip, and at the same time wrinkles the skin of the chin, expressing doubt or disdain. The Quadratus labii inferioris draws the lower lip directly downward and a little lateralward, as in the expression of irony. The Triangularis depresses the angle of the mouth, being the antagonist of the Caninus and Zygomaticus; acting with the Caninus, it will draw the angle of the mouth medialward.

The **Buccinator** (Fig. 485) is a thin quadrilateral muscle, occupying the interval between the maxilla and the mandible at the side of the face. It *arises* from the outer surfaces of the alveolar processes of the maxilla and mandible, corresponding to the three molar teeth; and behind, from the anterior border of the pterygomandibular raphé which separates it from the Constrictor pharyngis superior. The fibres converge toward the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the lower segment; the upper and lower fibres are continued forward into the corresponding lip without decussation.

Relations.—The Buccinator is covered by the buccopharyngeal fascia, and is in relation by its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the mandible, the Masseter, and a small portion of the Temporalis; this fat has been named the

suctorial pad, because it is supposed to assist in the act of sucking. In front the superficial surface of the Buccinator is in relation with the Zygomaticus, Risorius, Caninus, Triangularis, and the parotid duct which pierces it opposite the second molar tooth of the maxilla; the external maxillary artery and anterior facial vein cross it from below upward; it is also crossed by the branches of the facial and buccinator nerves. The *deep surface* is in relation with the buccal glands and mucous membrane of the mouth.

The **pterygomandibular raphé** (*pterygomandibular ligament*) is a tendinous band of the buccopharyngeal fascia, attached by one extremity to the hamulus of the medial pterygoid plate, and by the other to the posterior end of the mylohyoid line of the mandible. Its *medial surface* is covered by the mucous membrane of the mouth. Its *lateral surface* is separated from the ramus of the mandible by a quantity of adipose tissue. Its *posterior border* gives attachment to the Constrictor pharyngis superior; its *anterior border*, to part of the Buccinator (Fig. 485).

The **Orbicularis oris** (Fig. 486) is not a simple sphincter muscle like the Orbicularis oculi; it consists of numerous strata of muscular fibres surrounding the orifice of the mouth but having different direction. It consists partly of fibres derived from the other facial muscles which are inserted into the lips, and partly of fibres proper to the lips. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of the Buccinator fibres—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the maxilla passing to the lower lip,

TRIANGULARIS

FIG. 485.—Muscles of the pharynx and cheek.

FIG. 486.—Scheme showing arrangement of fibres of Orbicularis oris.

and those from the mandible to the upper lip. The uppermost and lowermost fibres of the Buccinator pass across the lips from side to side without decussation. Superficial to this stratum is a second, formed on either side by the Caninus and Triangularis, which cross each other at the angle of the mouth; those from the Caninus passing to the lower lip, and those from the Triangularis to the upper lip, along which they run, to be inserted into the skin near the median line. In addition to these there are fibres from the Quadratus labii superioris, the Zygomaticus, and the Quadratus labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane, through the thickness of the lip. Finally there are fibres by which the muscle is connected with the maxillæ and the septum of the nose above and with

the mandible below. In the upper lip these consist of two bands, lateral and medial, on either side of the middle line; the **lateral band** (*m. incisivus labii superioris*) arises from the alveolar border of the maxilla, opposite the lateral incisor tooth, and arching lateralward is continuous with the other muscles at the angle of the mouth; the **medial band** (*m. nasolabialis*) connects the upper lip to the back of the septum of the nose. The interval between the two medial bands corresponds with the depression, called the **philtrum**, seen on the lip beneath the septum of the nose. The additional fibres for the lower lip constitute a slip (*m. incisivus labii inferioris*) on either side of the middle line; this arises from the mandible, lateral to the Mentalis, and intermingles with the other muscles at the angle of the mouth.

The **Risorius** arises in the fascia over the Masseter and, passing horizontally forward, superficial to the Platysma, is inserted into the skin at the angle of the mouth (Fig. 483). It is a narrow bundle of fibres, broadest at its origin, but varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve.

Actions.—The Orbicularis oris in its ordinary action effects the direct closure of the lips; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forward. The Buccinators compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet; hence the name (*buccina*, a trumpet). The Risorius retracts the angle of the mouth, and produces an unpleasant grinning expression.

IV. THE MUSCLES OF MASTICATION.

The chief muscles of mastication are:

Masseter.
Temporalis.

Pterygoideus externus.
Pterygoideus internus.

Parotidomasseteric Fascia (*masseteric fascia*).—Covering the Masseter, and firmly connected with it, is a strong layer of fascia derived from the deep cervical fascia. Above, this fascia is attached to the lower border of the zygomatic arch, and behind, it invests the parotid gland.

The **Masseter** (Fig. 483) is a thick, somewhat quadrilateral muscle, consisting of two portions, superficial and deep. The **superficial portion**, the larger, *arises* by a thick, tendinous aponeurosis from the zygomatic process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch: its fibres pass downward and backward, to be *inserted* into the angle and lower half of the lateral surface of the ramus of the mandible. The **deep portion** is much smaller, and more muscular in texture; it *arises* from the posterior third of the lower border and from the whole of the medial surface of the zygomatic arch; its fibres pass downward and forward, to be *inserted* into the upper half of the ramus and the lateral surface of the coronoid process of the mandible. The deep portion of the muscle is partly concealed, in front, by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are continuous at their insertion.

Relations.—The Masseter is in relation by its *superficial surface* with the integument, Platysma, Risorius, Zygomaticus, the parotid gland and its accessory portion; the parotid duct, the branches of the facial nerve and the transverse facial vessels cross it. By its *deep surface*, it is in relation with the insertion of the Temporalis and the ramus of the mandible; a mass of fat separates it from the Buccinator and the buccinator nerve. The masseteric nerve and artery enter the muscle on its deep surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin* projects over the Buccinator and is crossed below by the anterior facial vein.

Temporal Fascia.—The temporal fascia covers the Temporalis muscle. It is a strong, fibrous investment, covered, laterally, by the Auricularis anterior and superior, by the galea aponeurotica, and by part of the Orbicularis oculi. The superficial temporal vessels and the auriculotemporal nerve cross it from below upward. Above, it is a single layer, attached to the entire extent of the superior temporal line; but below, where it is fixed to the zygomatic arch, it consists of two layers, one of which is inserted into the lateral, and the other into the medial border of the arch. A small quantity of fat, the orbital branch of the superficial temporal artery, and a filament from the zygomatic branch of the maxillary nerve, are contained between these two layers. It affords attachment by its deep surface to the superficial fibres of the Temporalis.

Dissection.—In order to expose the Temporalis, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma and dissecting it upward from the surface of the muscle. The zygomatic arch should then be divided in front at its junction with the zygomatic bone, and behind near the external auditory meatus, and drawn downward with the Masseter, which should be detached from its insertion into the ramus and angle of the mandible. The whole extent of the Temporalis is then exposed.

FIG. 487.—The Temporalis, the zygomatic arch and Masseter have been removed.

The **Temporalis** (*Temporal muscle*) (Fig. 487) is a broad, radiating muscle, situated at the side of the head. It arises from the whole of the temporal fossa (except that portion of it which is formed by the zygomatic bone) and from the deep surface of the temporal fascia. Its fibres converge as they descend, and end in a tendon, which passes deep to the zygomatic arch and is inserted into the medial surface, apex, and anterior border of the coronoid process, and the anterior border of the ramus of the mandible nearly as far forward as the last molar tooth.

Relations.—The Temporalis is in relation by its *superficial surface* with the integument, the Auricularis anterior and superior, the temporal fascia, the superficial temporal vessels, the auriculotemporal nerve, the temporal branches of the facial and zygomatic nerves, the galea aponeurotica, the zygomatic arch, and the Masseter. By its *deep surface*, it is in relation with the temporal fossa, the Pterygoideus externus and part of the Buccinator, the internal maxillary artery, and its deep temporal branches, the deep temporal nerves, and the buccinator vessels and nerve. Behind the tendon are the masseteric vessels and nerve. Its *anterior border* is separated from the zygomatic bone by a mass of fat.

Dissection.—The Temporalis having been examined, saw through the base of the coronoid process and draw it upward, together with the Temporalis, which should be detached from the surface of the temporal fossa. Divide the ramus of the mandible just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment, and the Pterygoidei will be exposed.

The **Pterygoideus externus** (*External pterygoid muscle*) (Fig. 488) is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the infratemporal fossa and the condyle of the mandible. It *arises* by two heads; an *upper* from the lower part of the lateral surface of the great wing of the sphenoid and from the infratemporal crest; a *lower* from the lateral surface of the lateral pterygoid plate. Its fibres pass horizontally backward and lateralward, to be *inserted* into a depression in front of the neck of the condyle of the mandible, and into the front margin of the articular disk of the temporomandibular articulation.

FIG. 488.—The Pterygoidei; the zygomatic arch and a portion of the ramus of the mandible have been removed.

Relations.—Its *superficial surface* is in relation with the ramus of the mandible, the internal maxillary artery, which crosses it,¹ the tendon of the Temporalis, and the Masseter. Its *deep surface* rests against the upper part of the Pterygoideus internus, the sphenomandibular ligament, the middle meningeal artery, and the mandibular nerve; its *upper border* is in relation with the temporal and masseteric branches of the mandibular nerve; its *lower border* with the lingual and inferior alveolar nerves. The buccal nerve and the internal maxillary artery pass between the two portions of the muscle (Fig. 488).

The **Pterygoideus internus** (*Internal pterygoid muscle*) (Fig. 488) is a thick, quadrilateral muscle. It *arises* from the medial surface of the lateral pterygoid plate and the grooved surface of the pyramidal process of the palatine bone; it has a second slip of origin from the lateral surfaces of the pyramidal process of the palatine and tuberosity of the maxilla. Its fibres pass downward, lateralward, and backward, and are *inserted*, by a strong tendinous lamina, into the lower and back part of the medial surface of the ramus and angle of the mandible, as high as the mandibular foramen.

Relations.—Its *lateral surface* is in relation with the ramus of the mandible, from which it is separated, at its upper part, by the Pterygoideus externus, the sphenomandibular ligament, the internal maxillary artery, the inferior alveolar vessels and nerve, the lingual nerve, and a process of the parotid gland. Its *medial surface* is in relation with the Tensor veli palatini, being separated from the Constrictor pharyngis superior by some areolar tissue.

¹ In many cases the artery will be found under cover of the muscle.

Nerves.—The muscles of mastication are supplied by the mandibular nerve.

Actions.—The Temporalis, Masseter, and Pterygoideus internus *raise* the mandible against the maxillæ with great force. The Pterygoideus externus assists in opening the mouth, but its main action is to draw forward the condyle and articular disk so that the mandible is protruded and the inferior incisors projected in front of the upper; in this action it is assisted by the Pterygoideus internus. The mandible is retracted by the posterior fibres of the Temporalis. If the Pterygoidei internus and externus of one side act, the corresponding side of the mandible is drawn forward while the opposite condyle remains comparatively fixed, and side-to-side movements, such as occur during the trituration of food, take place.

THE FASCIÆ AND MUSCLES OF THE ANTERO-LATERAL REGION OF THE NECK.

The antero-lateral muscles of the neck may be arranged into the following groups:

- | | |
|--------------------------|------------------------------|
| I. Superficial Cervical. | III. Supra- and Infra-hyoid. |
| II. Lateral Cervical. | IV. Anterior Vertebral. |
| V. Lateral Vertebral. | |

I. THE SUPERFICIAL CERVICAL MUSCLE.

Platysma.

Dissection.—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions, one from the chin, along the margin of the mandible, to the mastoid process, and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sternocleidomastoideus, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in Fig. 482, the superficial fascia will be exposed.

The **Superficial Fascia** of the neck is a thin lamina investing the Platysma, and is hardly demonstrable as a separate membrane.

The **Platysma** (Fig. 483) is a broad sheet *arising* from the fascia covering the upper parts of the Pectoralis major and Deltoideus; its fibres cross the clavicle, and proceed obliquely upward and medialward along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres cross the mandible, some being inserted into the bone below the oblique line, others into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the zygomaticus, or to the margin of the Orbicularis oculi. Beneath the Platysma, the external jugular vein descends from the angle of the mandible to the clavicle.

Actions.—When the entire Platysma is in action it produces a slight wrinkling of the surface of the skin of the neck in an oblique direction. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth in the expression of melancholy.

Nerve.—The Platysma is supplied by the cervical branch of the facial nerve.

II. THE LATERAL CERVICAL MUSCLES.

The lateral muscles are:

Trapezius and Sternocleidomastoideus.

The Trapezius is described on page 522.

The Fascia Colli (*deep cervical fascia*) (Fig. 489).—The fascia colli lies under cover of the Platysma, and invests the neck; it also forms sheaths for the carotid vessels, and for the structures situated in front of the vertebral column.

FIG. 489.—Section of the neck at about the level of the sixth cervical vertebra. Showing the arrangement of the fascia colli.

The investing portion of the fascia is attached behind to the ligamentum nuchae and to the spinous process of the seventh cervical vertebra. It forms a thin investment to the Trapezius, and at the anterior border of this muscle is continued forward as a rather loose areolar layer, covering the posterior triangle of the neck, to the posterior border of the Sternocleidomastoideus, where it begins to assume the appearance of a fascial membrane. Along the hinder edge of the Sternocleidomastoideus it divides to enclose the muscle, and at the anterior margin again forms a single lamella, which covers the anterior triangle of the neck, and reaches forward to the middle line, where it is continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is attached to the symphysis menti and the body of the hyoid bone.

Above, the fascia is attached to the superior nuchal line of the occipital, to the mastoid process of the temporal, and to the whole length of the inferior border of the body of the mandible. Opposite the angle of the mandible the fascia is very strong, and binds the anterior edge of the Sternocleidomastoideus firmly to that bone. Between the mandible and the mastoid process it ensheathes the parotid gland—the layer which covers the gland extends upward under the name of the **parotidomasseteric fascia** and is fixed to the zygomatic arch. From the part which passes under the parotid gland a strong band extends upward to the styloid process, forming the **stylomandibular ligament**. Two other bands may be defined: the **sphenomandibular** (page 395) and the **pterygospinous ligaments**. The **pterygospinous ligament** stretches from the upper part of the posterior border of the lateral pterygoid plate to the spinous process of the sphenoid. It occasionally ossifies, and in such cases, between its upper border and the base of the skull, a foramen is formed which transmits the branches of the mandibular nerve to the muscles of mastication.

Below, the fascia is attached to the acromion, the clavicle, and the manubrium sterni. Some little distance above the last it splits into two layers, superficial and deep. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers is a slit-like interval, the **suprasternal space** (*space of Burns*); it contains a small quantity of areolar tissue, the lower portions of the anterior jugular veins and their transverse connecting branch, the sternal heads of the Sternocleidomastoidei, and sometimes a lymph gland.

The fascia which lines the deep surface of the Sternocleidomastoideus gives off the following processes: (1) A process envelops the tendon at the Omohyoideus, and binds it down to the sternum and first costal cartilage. (2) A strong sheath, the **carotid sheath**, encloses the carotid artery, internal jugular vein, and vagus nerve. (3) The **prevertebral fascia** extends medialward behind the carotid vessels, where it assists in forming their sheath, and passes in front of the prevertebral muscles. It forms the posterior limit of a fibrous compartment, which contains the larynx and trachea, the thyroid gland, and the pharynx and œsophagus. The prevertebral fascia is fixed above to the base of the skull, and below is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid sheath and along its medial aspect the prevertebral fascia gives off a thin lamina, the **buccopharyngeal fascia**, which closely invests the Constrictor muscles of the pharynx, and is continued forward from the Constrictor pharyngis superior on to the Buccinator. It is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the **retropharyngeal space**, is found between them. This space is limited above by the base of the skull, while below it extends behind the œsophagus into the posterior mediastinal cavity of the thorax. The prevertebral fascia is prolonged downward and lateralward behind the carotid vessels and in front of the Scaleni, and forms a sheath for the brachial nerves and subclavian vessels in the posterior triangle of the neck; it is continued under the clavicle as the axillary sheath and is attached to the deep surface of the coracoclavicular fascia. Immediately above and behind the clavicle an areolar space exists between the investing layer and the sheath of the subclavian vessels, and in this space are found the lower part of the external jugular vein, the descending claviculæ nerves, the transverse scapular and transverse cervical vessels, and the inferior belly of the Omohyoideus muscle. This space is limited below by the fusion of the coracoclavicular fascia with the anterior wall of the axillary sheath. (4) The **pretracheal fascia** extends medially in front of the carotid vessels, and assists in forming the carotid sheath. It is continued behind the depressor muscles of the hyoid bone, and, after enveloping the thyroid gland, is prolonged in front of the trachea to meet the corresponding layer of the opposite side. Above, it is fixed to the hyoid bone, while below it is carried downward in front of the trachea and large vessels

at the root of the neck, and ultimately blends with the fibrous pericardium. This layer is fused on either side with the prevertebral fascia, and with it completes the compartment containing the larynx and trachea, the thyroid gland, and the pharynx and œsophagus.¹

Applied Anatomy.—The deep cervical fascia is of considerable importance from a surgical point of view. The investing layer opposes the extension of abscesses toward the surface, and pus forming beneath it has a tendency to extend laterally. If the pus be contained in the anterior triangle, it may find its way into the anterior mediastinal cavity, in front of the layer of fascia which passes down into the thorax to blend with the pericardium; but owing to the less density and thickness of the fascia in this situation it more frequently finds its way to the surface and points above the sternum. Pus forming beneath the pretracheal layer would in all probability find its way into the posterior mediastinal cavity. Pus forming behind the prevertebral layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, may extend toward the lateral part of the neck and point in the posterior triangle, or may perforate this layer of fascia and the buccopharyngeal fascia and point into the pharynx (*retropharyngeal abscess*).

In cases of cut throat, when the wound involves only the investing layer the injury is usually trivial, the special danger being injury to the external jugular vein, and the special complication, diffuse cellulitis. But where the second of the two layers is opened up, important structures may be injured, and serious results follow.

The sternal head of origin of the Sternocleidomastoideus is contained in the suprasternal space, so that this space is opened in division of this tendon. The lower part of the anterior jugular vein is also contained in the same space.

The **Sternocleidomastoideus** (*Sternomastoid muscle*) (Fig. 490) passes obliquely across the side of the neck. It is thick and narrow at its central part, but broader and thinner at either end. It *arises* from the sternum and clavicle by two heads. The **medial** or **sternal head** is a rounded fasciculus, tendinous in front, fleshy behind, which *arises* from the upper part of the anterior surface of the manubrium sterni, and is directed upward, lateralward, and backward. The **lateral** or **clavicular head**, composed of fleshy and aponeurotic fibres, *arises* from the superior border and anterior surface of the medial third of the clavicle; it is directed almost vertically upward. The two heads are separated from one another at their origins by a triangular interval, but gradually blend, below the middle of the neck, into a thick, rounded muscle which is *inserted*, by a strong tendon, into the lateral surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line of the occipital bone.

The Sternocleidomastoideus varies much in its extent of origin from the clavicle: in some cases the clavicular may be as narrow as the sternal head; in others, as much as 7.5 cm. in breadth. When the clavicular origin is broad, it is occasionally subdivided into several slips, separated by narrow intervals. More rarely, the adjoining margins of the Sternocleidomastoideus and Trapezius have been found in contact.

Triangles of the Neck.—This muscle divides the quadrilateral area of the side of the neck into two triangles, an anterior and a posterior. The boundaries of the **anterior triangle** are, in *front*, the median line of the neck; *above*, the lower border of the body of the mandible, and an imaginary line drawn from the angle of the mandible to the Sternocleidomastoideus; *behind*, the anterior border of the Sternocleidomastoideus. The apex of the triangle is at the upper border of the sternum. The boundaries of the **posterior triangle** are, in *front*, the posterior border of the Sternocleidomastoideus; *below*, the middle third of the clavicle; *behind*, the anterior margin of the Trapezius. The apex corresponds with the meeting of the Sternocleidomastoideus and Trapezius on the occipital bone. The anatomy of these triangles will be more fully described with that of the vessels of the neck (p. 642).

Relations.—The *superficial surface* of the Sternocleidomastoideus is in relation with the integument and Platysma, from which it is separated by the external jugular vein, several of the superficial branches of the cervical plexus, and the investing layer of the deep cervical fascia. The *deep surface* of the muscle is in relation with the sternoclavicular articulation, the process of the deep cervical fascia which binds the inferior belly of the Omohyoideus to the sternum and clavicle, the Sternohyoideus, Sternothyroideus, Omohyoideus, posterior belly of

¹ F. G. Parsons (Journal of Anatomy and Physiology, vol. xlv) regards the carotid sheath and the fascial planes in the neck as structures which are artificially produced by dissection.

the Digastricus, Levator scapulae, Splenius and Scaleri muscles, the common carotid artery, the internal and anterior jugular veins, the origins of the internal and external carotid arteries, the occipital, subclavian, transverse cervical, and transverse scapular arteries and veins, the phrenic, vagus, hypoglossal, descendens and communicantes hypoglossi nerves, the accessory nerve which pierces its upper third, the cervical plexus, the upper part of the brachial plexus, parts of the thyroid and parotid glands and their vessels, and the deep cervical lymph glands.

Actions.—When only one Sternocleidomastoideus acts, it draws the head toward the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face toward the opposite side. Acting together from their sternoclavicular attachments the muscles will flex the cervical part of the vertebral column. If the head be fixed, the two muscles assist in elevating the thorax in forced inspiration.

FIG. 490.—Muscles of the neck. Lateral view

Nerves.—The Sternocleidomastoideus is supplied by the accessory nerve and branches from the anterior divisions of the second and third cervical nerves.

Applied Anatomy.—The surgical anatomy of the Sternocleidomastoideus is of importance in connection with the deformity known as *wry-neck*, which is due to a contracted condition of this muscle. The wry-neck may be temporary, as the result of direct irritation of the muscle or of the nerves supplying it, and may occur in acute glandular enlargement, cellulitis of the neck, myositis of the muscle, or cervical caries. It may, however, be permanent, and is then most often due to injury to the muscle during birth, especially in breech presentations, rupture of the fibres and subsequent cicatricial contraction taking place. In these cases, division of the muscle is often necessary to effect a cure, and this may be done either subcutaneously or through an open wound. The subcutaneous method is thus performed; the external jugular artery and jugular veins having been, if possible, defined, a tenotomy knife is introduced close above the origin of one tendon of the muscle, about 1.25 cm. above the clavicle, and the tenal spine on flat behind the tendon and then turned forward, and the tendon divided from downward, to while the muscle is put well upon the stretch by an assistant. The other tendon it lies in connection a similar manner. In dividing the clavicular origin, it is always desirable to tenotome along the posterior border, in order to avoid the external jugular vein. It is, however, much to be preferred, as being the more effectual and the less dashed by the myotomies are taken to keep the wound aseptic. The tendons of origin are freely of the Digastricus, zontal incision across the root of the neck and carefully divided, any tense br

exist should also be divided. The wound is now sutured and dressed, and the head fixed in as straight a position as possible.

There is also a condition coming on in adult life (*spasmodic torticollis*) which is a very distressing form of functional nervous disease. It begins with tonic or clonic spasm of one of the Sternocleidomastoidei, which is soon followed by spasm of the Trapezius, particularly its clavicular portion. The Splenius of the opposite side, the Scaleri, Semispinales capitis, and Longissimi capitis may all become involved in turn, with secondary contracture of the deep cervical fascia. Operation in these cases often fails to give satisfactory results. Tenotomy of the affected muscles or section of the nerves supplying them may afford temporary relief, but the spasm often returns when the cut nerves or muscles rejoin.

III. THE SUPRA- AND INFRAHYOID MUSCLES (Figs. 490, 491).

The suprahyoid muscles are:

Digastricus.

Stylohyoideus.

Mylohyoideus.

Geniohyoideus.

Dissection.—To dissect these muscles a block should be placed beneath the back of the neck, and the head drawn backward and retained in that position. On the removal of the deep fascia the muscles are at once exposed.

Symphysis

FIG. 491.—Muscles of the neck. Anterior view.

of The **Digastricus** (*Digastric muscle*) consists of two fleshy bellies united by an of the mediate rounded tendon. It lies below the body of the mandible, and extends, Trapezius and form, from the mastoid process to the symphysis menti. The posterior with that of

Relations. r than the anterior, arises from the mastoid notch of the temporal ment and Platyses downward and forward. The anterior belly arises from a depression superficial brancide of the lower border of the mandible, close to the symphysis, and The deep surface ard and backward. The two bellies end in an intermediate tendon cess of the deep s the Stylohyoideus muscle, and is held in connection with the side sternum and clavi the greater cornu of the hyoid bone by a fibrous loop, which is by a mucous sheath. A broad aponeurotic layer is given off

¹ F G Parsons (Jour in the neck as structures

from the tendon of the Digastricus on either side, to be attached to the body and greater cornu of the hyoid bone; this is termed the **suprahyoid aponeurosis**.

The Digastricus divides the anterior triangle of the neck into three smaller triangles (1) the **submaxillary triangle**, bounded above by the lower border of the body of the mandible, and a line drawn from its angle to the Sternocleidomastoideus, below by the posterior belly of the Digastricus and the Stylohyoideus, in front by the anterior belly of the Digastricus; (2) the **carotid triangle**, bounded above by the posterior belly of the Digastricus and Stylohyoideus, behind by the Sternocleidomastoideus, below by the Omohyoideus; (3) the **suprahyoid or submental triangle**, bounded laterally by the anterior belly of the Digastricus, medially by the middle line of the neck from the hyoid bone to the symphysis menti, and inferiorly by the body of the hyoid bone.

Relations.—The Digastricus is in relation by its *superficial surface* with the Platysma, Sternocleidomastoideus, part of the Splenius, Longissimus capitis, mastoid process, Stylohyoideus, and the parotid gland. The *deep surface* of the anterior belly lies on the Mylohyoideus; that of the posterior belly on the Styloglossus, Stylopharyngeus, and Hyoglossus muscles, the external carotid artery and its occipital, lingual, external maxillary, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylohyoideus** (*Stylohyoid muscle*) is a slender muscle, lying in front of, and above, the posterior belly of the Digastricus. It *arises* from the back and lateral surface of the styloid process, near the base; and, passing downward and forward, is *inserted* into the body of the hyoid bone, at its junction with the greater cornu, and just above the Omohyoideus. It is perforated, near its insertion, by the tendon of the Digastricus.

The **Stylohyoid Ligament** (*ligamentum stylohyoideus*).—In connection with the Stylohyoideus muscle a ligamentous band, the **stylohyoid ligament**, may be described. It is a fibrous cord, which is attached to the tip of the styloid process of the temporal and the lesser cornu of the hyoid bone. It frequently contains a little cartilage in its centre, is often partially ossified, and in many animals forms a distinct bone, the **epihyal**.

The **Mylohyoideus** (*Mylohyoid muscle*), flat and triangular, is situated immediately above the anterior belly of the Digastricus, and forms, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It *arises* from the whole length of the mylohyoid line of the mandible, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass medialward and slightly downward, to be *inserted* into the body of the hyoid bone. The middle and anterior fibres are *inserted* into a median fibrous raphé extending from the symphysis menti to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. This median raphé is sometimes wanting; the fibres of the two muscles are then continuous.

Relations.—The Mylohyoideus is in relation by its *superficial or under surface* with the Platysma, the anterior belly of the Digastricus, the suprahyoid aponeurosis, the superficial part of the submaxillary gland, the external maxillary and submental vessels, and the mylohyoid vessels and nerve. By its *deep or superior surface* it is in relation with the Geniohyoideus, part of the Hyoglossus, and the Styloglossus muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and the submaxillary duct, the lingual and sublingual vessels, and the buccal mucous membrane.

Dissection.—The Mylohyoideus should now be removed, in order to expose the muscles which lie beneath; this is effected by reflecting it from its attachments to the hyoid bone and mandible, and separating it by a vertical incision from its fellow of the opposite side.

The **Geniohyoideus** (*Geniohyoid muscle*) is a narrow muscle, situated above the medial border of the Mylohyoideus. It *arises* from the inferior mental spine on the back of the symphysis menti, and runs backward and slightly downward, to be *inserted* into the anterior surface of the body of the hyoid bone; it lies in contact with its fellow of the opposite side.

Nerves.—The Mylohyoideus and anterior belly of the Digastricus are supplied by the mylohyoid branch of the inferior alveolar; the Stylohyoideus and posterior belly of the Digastricus, by the facial; the Geniohyoideus, by the hypoglossal.

Actions.—These muscles perform two very important actions. During the act of deglutition they raise the hyoid bone, and with it the base of the tongue; when the hyoid bone is fixed by its depressors and those of the larynx, they depress the mandible. During the first act of deglutition, when the mass of food is being driven from the mouth into the pharynx, the hyoid bone and with it the tongue, is carried upward and forward by the anterior bellies of the Digastrici, the Mylohyoidei, and Geniohyoidei. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upward and backward by the posterior bellies of the Digastrici and the Stylohyoidei, which assist in preventing the return of the food into the mouth.

The infrahyoid muscles are:

Sternohyoideus.
Sternothyreoideus.

Thyreohyoideus.
Omohyoideus.

Dissection.—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the Omohyoideus it is necessary to divide the Sternocleidomastoideus at its centre, and turn its ends aside, and to detach the Trapezius from the clavicle and scapula. This, however, should not be done until the Trapezius has been dissected.

The **Sternohyoideus** (*Sternohyoid muscle*) is a thin, narrow muscle, which arises from the posterior surface of the medial end of the clavicle, the posterior sternoclavicular ligament, and the upper and posterior part of the manubrium sterni. Passing upward and medialward, it is *inserted*, by short, tendinous fibres, into the lower border of the body of the hyoid bone. Below, this muscle is separated from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and from this upward, lie side by side. It sometimes presents, immediately above its origin, a transverse tendinous inscription.

The **Sternothyreoideus** (*Sternothyroid muscle*) is shorter and wider than the preceding muscle, beneath which it is situated. It arises from the posterior surface of the manubrium sterni, below the origin of the Sternohyoideus, and from the edge of the cartilage of the first rib, and sometimes that of the second rib, it is *inserted* into the oblique line on the lamina of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck, but diverges somewhat as it ascends; it is occasionally traversed by a transverse or oblique tendinous inscription.

The **Thyreohyoideus** (*Thyrohyoid muscle*) is a small, quadrilateral muscle appearing like an upward continuation of the Sternothyreoideus. It arises from the oblique line on the lamina of the thyroid cartilage, and is *inserted* into the lower border of the greater cornu of the hyoid bone.

The **Omohyoideus** (*Omohyoid muscle*) consists of two fleshy bellies united by a central tendon. It arises from the upper border of the scapula, and occasionally from the superior transverse ligament which crosses the scapular notch, its extent of attachment to the scapula varying from a few millimetres to 2.5 cm. From this origin, the inferior belly forms a flat, narrow fasciculus, which inclines forward and slightly upward across the lower part of the neck, being bound down to the clavicle by a fibrous expansion; it then passes behind the Sternocleidomastoideus, becomes tendinous and changes its direction, forming an obtuse angle. It ends in the superior belly, which passes almost vertically upward, close to the lateral border of the Sternohyoideus, to be inserted into the lower border of the body of the hyoid bone, lateral to the insertion of the Sternohyoideus. The central tendon of this muscle varies much in length and form, and is held in position by a process of the deep cervical fascia, which sheaths it, and is prolonged down to be attached to the clavicle and first rib; it is by this means that the angular form of the muscle is maintained.

The inferior belly of the Omohyoideus divides the posterior triangle of the neck into an upper or **occipital triangle** and a lower or **subclavian triangle**, while its superior belly divides the anterior triangle into an upper or **carotid triangle** and a lower or **muscular triangle**.

Nerves.—The Thyreohyoideus is supplied by a branch from the hypoglossal nerve; the superior belly of the Omohyoideus by the descendens hypoglossi; the Sternohyoideus, Sternothyreodeus, and inferior belly of the Omohyoideus are supplied by branches from the loop between the descendens hypoglossi and descendens cervicalis.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omohyoidei not only depress the hyoid bone, but carry it backward and to one or the other side. They are concerned especially in prolonged inspiratory efforts; for by rendering the lower part of the cervical fascia tense they lessen the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. The Thyreohyoideus may act as an elevator of the thyroid cartilage, when the hyoid bone ascends, drawing the thyroid cartilage up behind the hyoid bone. The Sternothyreodeus acts as a depressor of the thyroid cartilage.

IV. THE ANTERIOR VERTEBRAL MUSCLES (Fig. 492).

The anterior vertebral muscles are:

Longus colli.
Longus capitis.

Rectus capitis anterior.
Rectus capitis lateralis.

FIG. 492.—The anterior vertebral muscles.

The **Longus colli** is situated on the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is broad in the middle, narrow and pointed at either end, and consists of three portions, a superior oblique,

an inferior oblique, and a vertical. The **superior oblique portion** arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ; and, ascending obliquely with a medial inclination, is *inserted* by a narrow tendon into the tubercle on the anterior arch of the atlas. The **inferior oblique portion**, the smallest part of the muscle, arises from the front of the bodies of the first two or three thoracic vertebræ; and, ascending obliquely in a lateral direction, is *inserted* into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The **vertical portion** arises, below, from the front of the bodies of the upper three thoracic and lower three cervical vertebræ, and is *inserted* into the front of the bodies of the second, third, and fourth cervical vertebræ.

The **Longus capitis** (*Rectus capitis anticus major*), broad and thick above, narrow below, arises by four tendinous slips, from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and ascends, converging toward its fellow of the opposite side, to be *inserted* into the inferior surface of the basilar part of the occipital bone.

The **Rectus capitis anterior** (*Rectus capitis anticus minor*) is a short, flat muscle, situated immediately behind the upper part of the Longus capitis. It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process, and passing obliquely upward and medialward, is *inserted* into the inferior surface of the basilar part of the occipital bone immediately in front of the foramen magnum.

The **Rectus capitis lateralis**, a short, flat muscle, arises from the upper surface of the transverse process of the atlas, and is *inserted* into the under surface of the jugular process of the occipital bone.

Nerves.—The Rectus capitis anterior and the Rectus capitis lateralis are supplied from the loop between the first and second cervical nerves; the Longus capitis, by branches from the first, second, and third cervical; the Longus colli, by branches from the second to the seventh cervical nerves.

Actions.—The Longus capitis and Rectus capitis anterior are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backward. These muscles also flex the head, and from their obliquity, rotate it, so as to turn the face to one or the other side. The Rectus lateralis, acting on one side, bends the head laterally. The Longus colli flexes and slightly rotates the cervical portion of the vertebral column.

V. THE LATERAL VERTEBRAL MUSCLES (Fig. 492).

The lateral vertebral muscles are:

Scalenus anterior.

Scalenus posterior.

Scalenus medius.

The **Scalenus anterior** (*Scalenus anticus*) lies deeply at the side of the neck, behind the Sternocleidomastoideus. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and descending, almost vertically, is *inserted* by a narrow, flat tendon into the scalene tubercle on the inner border of the first rib, and into the ridge on the upper surface of the rib in front of the subclavian groove.

Relations.—In front of the Scalenus anterior are the clavicle, the Subclavius, Sternocleidomastoideus, and Omohyoideus muscles, the transverse cervical, the transverse scapular, and ascending cervical arteries, the subclavian vein, and the phrenic nerve. By its *posterior surface*, it is in relation with the cords of the brachial plexus, the subclavian artery, and the pleura, which separate it from the Scalenus medius. Below, it is separated from the Longus colli by the vertebral artery, and above, from the Longus capitis, by the ascending cervical branch of the inferior thyroid artery.

The **Scalenus medius**, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical

vertebræ, and descending along the side of the vertebral column, is *inserted* by a broad attachment into the upper surface of the first rib, between the tubercle and the subclavian groove.

Relations.—The *Scalenus medius* is in relation by its *anterior surface* with the *Sternocleidomastoideus*; it is crossed by the clavicle and the *Omohyoideus*; the subclavian artery and the cervical nerves separate it from the *Scalenus anterior*. *Lateral* to it are the *Levator scapulae* and the *Scalenus posterior*. The long thoracic nerve is formed in the substance of the *Scalenus medius* and emerges from it; the dorsal scapular nerve also pierces it.

The ***Scalenus posterior*** (*Scalenus posticus*), the smallest and most deeply seated of the three *Scaleni*, *arises*, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebræ, and is *inserted* by a thin tendon into the outer surface of the second rib, behind the attachment of the *Serratus anterior*. It is occasionally blended with the *Scalenus medius*.

Nerves.—The *Scaleni* are supplied by branches from the second to the seventh cervical nerves.

Actions.—When the *Scaleni* act from above, they elevate the first and second ribs, and are, therefore, inspiratory muscles. Acting from below, they bend the vertebral column to one or other side; if the muscles of both sides act, the vertebral column is slightly flexed.

THE FASCIAE AND MUSCLES OF THE TRUNK.

The muscles of the trunk may be arranged in six groups:

- | | |
|------------------------------|------------------------------|
| I. Deep Muscles of the Back. | IV. Muscles of the Abdomen. |
| II. Suboccipital Muscles. | V. Muscles of the Pelvis. |
| III. Muscles of the Thorax. | VI. Muscles of the Perineum. |

I. THE DEEP MUSCLES OF THE BACK (Fig. 494).

The deep or intrinsic muscles of the back consist of a complex group of muscles extending from the pelvis to the skull. They are:

- | | |
|--------------------|---------------------|
| Splenius capitis. | Multifidus. |
| Splenius cervicis. | Rotatores. |
| Sacrospinalis. | Interspinales. |
| Semispinalis. | Intertransversarii. |

Dissection of the Muscles of the Back by Layers (Fig. 493).—*First Layer.*—Place the body in a prone position, with the arms extended over the sides of the table, and the thorax and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to the mastoid process, and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last thoracic vertebra, upward and outward to the acromion process. This incision corresponds with the lower border of the *Trapezius* muscle. The flaps of integument are then to be removed in the direction shown in the figure.

Second Layer.—The *Trapezius* must be removed, in order to expose the second layer; to effect this, detach the muscle from its attachment to the clavicle and spine of the scapula, and turn it back toward the vertebral column.

Third Layer.—To bring into view the third layer of muscles, remove the whole of the second, together with the *Latissimus dorsi*, by cutting through the *Levator scapulae* and *Rhomboides* muscles near their origin, and reflecting them downward, and by dividing the *Latissimus dorsi* in the middle by a vertical incision carried from its upper to its lower part, and reflecting the two halves of the muscle.

Fourth Layer.—To expose the muscles of the fourth layer, remove entirely the *Serrati* and the vertebral and lumbar fasciæ. Then detach the *Splenius* by separating its attachment to the spinous processes and reflecting it outward.

Fifth Layer.—Remove the muscles of the preceding layer by dividing and turning aside the *trapezius capitis*; then detach the *Spinalis* and *Longissimus dorsi* from their attachments, divide the *Sacrospinalis* at its connection below to the sacral lumbar vertebræ and turn it outward. The muscles filling up the interval between the spinous and transverse processes are then exposed.

The Lumbodorsal Fascia (*fascia lumbodorsalis*; *lumbar aponeurosis* and *vertebral scia*).—The lumbodorsal fascia is a deep investing membrane which covers the deep muscles of the back of the trunk. Above, it passes in front of the *Serratus posterior superior* and is continuous with a similar investing layer on the back of the neck—the **nuchal fascia**.

10. 493.—Dissection of the muscles of the back.

In the thoracic region the lumbodorsal fascia is a thin fibrous lamina which serves to bind down the Extensor muscles of the vertebral column and to separate them from the muscles connecting the vertebral column to the upper extremity. It contains both longitudinal and transverse fibres, and is attached, **medially**, to the spinous processes of the thoracic vertebræ; **laterally** to the angles of the ribs.

In the lumbar region the fascia (*lumbar aponeurosis*) is in two layers, anterior and posterior (Fig. 494). The posterior layer is attached to the spinous processes of the lumbar and sacral vertebræ and to the supraspinal ligament; the anterior is attached, **medially**, to the tips of the transverse processes of the lumbar vertebræ and to the intertransverse ligaments, **below**, to the iliolumbar ligament, and **above**, to the lumbo-costal ligament. The two layers unite at the lateral margin of the *Sacrospinalis*, to form the tendon of origin of the *Transversus abdominis*.

The **Splenius capitis** (Fig. 516) arises from the lower half of the *ligamentum nuchæ*, from the spinous process of the seventh cervical vertebræ, and from the spinous processes of the upper three or four thoracic vertebræ. The fibres of the muscle are directed upward and lateralward and

Lumbodorsal
fascia

Posterior layer

11. 494.—Diagram of a transverse section of the posterior abdominal wall, to show the disposition of the lumbodorsal fascia.

is inserted, under cover of the *Sternocleidomastoideus*, into the mastoid process of the temporal bone, and into the rough surface on the occipital bone just below the lateral third of the superior nuchal line.

The **Rectus capitis posterior major** (*Rectus capitis posticus major*) arises by a pointed tendon from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the lateral part of the inferior nuchal line of the occipital bone and the surface of the bone immediately below the line. As the muscles of the two sides pass upward and lateralward, they leave between them a triangular space, in which the *Recti capitis posteriores minores* are seen.

The **Rectus capitis posterior minor** (*Rectus capitis posticus minor*) arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, widening as it ascends, is inserted into the medial part of the inferior nuchal line of the occipital bone and the surface between it and the foramen magnum.

The **Obliquus capitis inferior** (*Obliquus inferior*), the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes lateralward and slightly upward, to be inserted into the lower and back part of the transverse process of the atlas.

The **Obliquus capitis superior** (*Obliquus superior*), narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding. It passes upward and medialward, and is inserted into the occipital bone, between the superior and inferior nuchal lines, lateral to the *Semispinalis capitis*.

The Suboccipital Triangle.—Between the *Obliqui* and the *Rectus capitis posterior major* is the **suboccipital triangle**. It is bounded, *above* and *medially*, by the *Rectus capitis posterior major*; *above* and *laterally*, by the *Obliquus capitis superior*; *below* and *laterally*, by the *Obliquus capitis inferior*. It is covered by a layer of dense fibro-fatty tissue, situated beneath the *Semispinalis capitis*. The floor is formed by the posterior occipitoatlantal membrane, and the posterior arch of the atlas. In the deep groove on the upper surface of the posterior arch of the atlas are the vertebral artery and the first cervical or suboccipital nerve.

Nerves.—The deep muscles of the back and the suboccipital muscles are supplied by the posterior primary divisions of the spinal nerves.

Actions.—The *Sacrospinalis* and its upward continuations and the *Spinales* serve to maintain the vertebral column in the erect posture; they also serve to bend the trunk backward when it is required to counterbalance the influence of any weight at the front of the body—as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the vertebral column being drawn backward, by the counterbalancing action of the *Sacrospinales*. The muscles which form the continuation of the *Sacrospinales* on to the head and neck steady those parts and fix them in the upright position. If the *Iliocostalis lumborum* and *Longissimus thoracis* of one side act, they serve to draw down the chest and vertebral column to the corresponding side. The *Iliocostales cervicis*, taking their fixed points from the cervical vertebrae, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. When both *Longissimi cervicis* act from below, they bend the neck backward. When both *Longissimi capitis* act from below; they bend the head backward; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two *Recti* draw the head backward. The *Rectus capitis posterior major*, owing to its obliquity, rotates the skull, with the atlas, around the odontoid process, turning the face to the same side. The *Multifidus* acts successively upon the different parts of the column; thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle acts upon the lumbar region; which in turn becomes the fixed point for the fasciculi moving the thoracic region, and so on throughout the entire length of the column. The *Multifidus* also serves to rotate the column, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the *Obliquus externus abdominis*. The *Obliquus capitis superior* draws the head backward and to its own side. The *Obliquus inferior* rotates the atlas, and with it the skull, around the odontoid process, turning the face to the same side. When the *Semispinales* of the two sides act together, they help to extend the vertebral column; when the muscles of only one side act, they rotate the thoracic and cervical parts of the column, turning the body to the opposite side. The *Semispinales capitis* draw the head directly backward; if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The *Interspinales* by approximating the spinous processes help to extend the column. The *Intertransversarii* approximate the transverse processes, and help to bend the column to one side. The *Rotatores* assist the *Multifidus* to rotate the vertebral column, so that the front of the trunk is turned to the side opposite to that from which the muscles act.

MYOLOGY

and Anatomy.—In cases of tuberculous caries of the vertebral bodies, and in other diseases of the vertebral column, rigidity of the spinal muscles is one of the earliest and most conspicuous symptoms. A child with commencing spinal disease always maintains the affected portion of the column in a state of absolute rigidity, to prevent the inflamed structures from being moved against each other; this is one of the best examples of nature's method of producing rest of the part.

III. THE MUSCLES OF THE THORAX.

muscles belonging to this group are the

Intercostales externi.	Levatores costarum.
Intercostales interni.	Serratus posterior superior.
Subcostales.	Serratus posterior inferior.
Transversus thoracis.	Diaphragma.

Costal Fasciae.—In each intercostal space thin but firm layers of fascia cover the outer surface of the *Intercostalis externus* and the inner surface of the *Intercostalis internus*; and a third, more delicate layer, is interposed between the two planes of muscular fibres. They are best marked in those situations where the muscular fibres are deficient, as between the *Intercostales externi* and sternum in front, and between the *Intercostales interni* and vertebral column behind.

Intercostales (*Intercostal muscles*) (Fig. 520) are two thin planes of muscular and fibrous fibres occupying each of the intercostal spaces. They are named *external* and *internal* from their surface relations—the external being superficial and the internal.

Intercostales externi (*External intercostals*) are *eleven* in number on either side. They extend from the tubercles of the ribs behind, to the cartilages of the ribs in front, where they end in thin membranes, the **anterior intercostal membranes**, which are continued forward to the sternum. Each *arises* from the lower border of the rib above, and is *inserted* into the upper border of the rib below. In the two lower intercostal spaces they extend to the ends of the cartilages, and in the upper two or three they do not quite reach the ends of the ribs. They are thicker than the *Intercostales interni*, and their fibres are directed obliquely downward and lateralward on the back of the thorax, and downward, forward, and medialward on the front.

Intercostales interni (*Internal intercostals*) are also *eleven* in number on either side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the false ribs, and extend backward as far as the angles of the ribs, whence they are continued to the vertebral column by thin aponeuroses, the **posterior intercostal membranes**. Each *arises* from the ridge on the inner surface of a rib, as well as from the corresponding costal cartilage, and is *inserted* into the upper border of the rib below. Their fibres are also directed obliquely, but pass in a direction opposite to those of the *Intercostales externi*.

Subcostales (*Infracostales*) consist of muscular and aponeurotic fasciculi, and are usually well-developed only in the lower part of the thorax; each *arises* from the inner surface of one rib near its angle, and is *inserted* into the inner surface of the second or third rib below. Their fibres run in the same direction as those of the *Intercostales interni*.

Transversus thoracis (*Triangularis sterni*) is a thin plane of muscular and fibrous fibres, situated upon the inner surface of the front wall of the chest (Fig. 526). It *arises* on either side from the lower third of the posterior surface of the body of the sternum, from the posterior surface of the xiphoid process, and from the sternal ends of the costal cartilages of the lower three or four true ribs. Its fibres diverge upward and lateralward, to be *inserted* by slips into the

lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the *Transversus abdominis*; the intermediate fibres are oblique, while the highest are almost vertical. This muscle varies in its attachments, not only in different subjects, but on opposite sides of the same subject.

The *Levatores costarum* (Fig. 495), twelve in number on either side, are small tendinous and fleshy bundles, which arise from the ends of the transverse processes of the seventh cervical and upper eleven thoracic vertebræ; they pass obliquely downward and lateralward, like the fibres of the *Intercostales externi*, and each is inserted into the outer surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (*Levatores costarum breves*). Each of the four lower muscles divides into two fasciculi, one of which is inserted as above described; the other passes down to the second rib below its origin (*Levatores costarum longi*).

The *Serratus posterior superior* (*Serratus posticus superior*) is a thin, quadrilateral muscle, situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the lower part of the ligamentum nuchæ, from the spinous processes of the seventh cervical and upper two or three thoracic vertebræ and from the supraspinal ligament. Inclining downward and lateralward it becomes muscular, and is inserted, by four fleshy digitations, into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

The *Serratus posterior inferior* (*Serratus posticus inferior*) (Fig. 516) is situated at the junction of the thoracic and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a wide interval. It arises by a thin aponeurosis from the spinous processes of the lower two thoracic and upper two or three lumbar vertebræ, and from the supraspinal ligament. Passing obliquely upward and lateralward, it becomes fleshy, and divides into four flat digitations, which are inserted into the inferior borders of the lower four ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbodorsal fascia.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

The *Diaphragma* (*Diaphragm*) (Figs. 497, 498) is a dome-shaped musculo-fibrous septum which separates the thoracic from the abdominal cavity, its convex upper surface forming the floor of the former, and its concave under surface the roof of the latter. Its peripheral part consists of muscular fibres which take origin from the circumference of the thoracic outlet and converge to be inserted into a central tendon.

FIG. 496.—Posterior surface of sternum and costal cartilages, showing *Transversus thoracis*.

The muscular fibres may be grouped according to their origins into three parts—sternal, costal, and lumbar. The **sternal part** *arises* by two fleshy slips from

Vena caval foramen

Aortic hiatus

FIG. 497.—Posterior half of Diaphragm. (Modified from model by His.)

Xiphoid process

Open

FIG. 498.—The Diaphragm. Under surface

the back of the xiphoid process; the **costal part** from the inner surfaces of the cartilages and adjacent portions of the lower six ribs on either side, interdigitating with the *Transversus abdominis*; and the **lumbar part** from aponeurotic arches, named the lumbocostal arches, and from the lumbar vertebræ by two pillars or **crura**. There are two lumbocostal arches, a medial and a lateral, on either side.

The **Medial Lumbocostal Arch** (*arcus lumbocostalis medialis* [Halleri]; *internal arcuate ligament*) is a tendinous arch in the fascia covering the upper part of the *Psoas major*; medially, it is continuous with the lateral tendinous margin of the corresponding crus, and is attached to the side of the body of the first or second lumbar vertebra; laterally, it is fixed to the front of the transverse process of the first and, sometimes also, to that of the second lumbar vertebra.

The **Lateral Lumbocostal Arch** (*arcus lumbocostalis lateralis* [Halleri]; *external arcuate ligament*) arches across the upper part of the *Quadratus lumborum*, and is attached, medially, to the front of the transverse process of the first lumbar vertebra, and, laterally, to the tip and lower margin of the twelfth rib.

The Crura.—At their origins the crura are tendinous in structure, and blend with the anterior longitudinal ligament of the vertebral column. The **right crus**, larger and longer than the left, *arises* from the anterior surfaces of the bodies and intervertebral fibrocartilages of the upper three lumbar vertebræ, while the **left crus** *arises* from the corresponding parts of the upper two only. The medial tendinous margins of the crura pass forward and medialward, and meet in the middle line to form an arch across the front of the aorta; this arch is often poorly defined.

From this series of origins the fibres of the *Diaphragma* converge to be inserted into the central tendon. The fibres arising from the xiphoid process are very short, and occasionally aponeurotic; those from the medial and lateral lumbocostal arches, and more especially those from the ribs and their cartilages, are longer, and describe marked curves as they ascend and converge to their insertion. The fibres of the crura diverge as they ascend, the most lateral being directed upward and lateralward to the central tendon. The medial fibres of the right crus ascend on the left side of the oesophageal hiatus, and occasionally a fasciculus of the left crus crosses the aorta and runs obliquely through the fibres of the right crus toward the vena caval foramen (Low¹).

The Central Tendon.—The central tendon of the *Diaphragma* is a thin but strong aponeurosis situated near the centre of the vault formed by the muscle, but somewhat closer to the front than to the back of the thorax, so that the posterior muscular fibres are the longer. It is situated immediately below the pericardium, with which it is partially blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions or leaflets separated from one another by slight indentations. The right leaflet is the largest, the middle, directed toward the xiphoid process, the next in size, and the left the smallest. In structure the tendon is composed of several planes of fibres, which intersect one another at various angles and unite into straight or curved bundles—an arrangement which gives it additional strength.

Openings in the Diaphragma.—The *Diaphragma* is pierced by a series of apertures to permit of the passage of structures between the thorax and abdomen. Three large openings—the **aortic**, the **oesophageal**, and the **vena caval**—and a series of smaller ones are described.

The **aortic hiatus** is the lowest and most posterior of the large apertures; it lies at the level of the twelfth thoracic vertebra. Strictly speaking, it is not an aperture in the *Diaphragma* but an osseaponeurotic opening between it and the vertebral column, and therefore behind the *Diaphragma*; occasionally some tendinous fibres prolonged across the bodies of the vertebræ from the medial parts of the lower ends of the crura pass behind the aorta, and thus convert the hiatus into a fibrous ring.

The hiatus is situated slightly to the left of the middle line, and is bounded in front by the crura, and behind by the body of the first lumbar vertebra. Through it pass the aorta, the azygos vein, and the thoracic duct; occasionally the azygos vein is transmitted through the right crus.

The **oesophageal hiatus** is situated in the muscular part of the Diaphragma at the level of the tenth thoracic vertebra, and is elliptical in shape. It is placed above, in front, and a little to the left of the aortic hiatus, and transmits the oesophagus, the vagus nerves, and some small oesophageal arteries.

The **vena caval foramen** is the highest of the three, and is situated about the level of the fibrocartilage between the eighth and ninth thoracic vertebræ. It is quadrilateral in form, and is placed at the junction of the right and middle leaflets of the central tendon, so that its margins are tendinous. It transmits the inferior vena cava, the wall of which is adherent to the margins of the opening, and some branches of the right phrenic nerve.

Of the **lesser apertures**, two in the right crus transmit the greater and lesser right splanchnic nerves; three in the left crus give passage to the greater and lesser left splanchnic nerves and the hemiazygos vein. The gangliated trunks of the sympathetic usually enter the abdominal cavity behind the Diaphragma, under the medial lumbocostal arches. The structures piercing the crura are sometimes utilized to divide each crus into three parts—medial, intermediate, and lateral. Between the medial and intermediate crura pass the hemiazygos vein and the splanchnic nerves; between the intermediate crus and the lateral crus (which consists of the fibres rising from the medial lumbocostal arch) the gangliated trunks pass.

On either side two small intervals exist at which the muscular fibres of the Diaphragma are deficient and are replaced by areolar tissue. One between the sternal and costal parts transmits the superior epigastric branch of the internal mammary artery and some lymphatics from the abdominal wall and convex surface of the liver. The other, between the fibres springing from the medial and lateral lumbocostal arches, is less constant; when this interval exists, the upper and back part of the kidney is separated from the pleura by areolar tissue only.

Relations.—The upper surface of the Diaphragma is in relation with three serous membranes, viz., on either side the pleura, which separates it from the base of the corresponding lung, and on the middle leaflet of the central tendon the pericardium, which intervenes between it and the heart. The central portion lies on a slightly lower level than the summits of the lateral portions. The greater part of the under surface is covered by the peritoneum. The right side is accurately moulded over the convex surface of the right lobe of the liver, the right kidney, and right suprarenal gland; the left over the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney, and left suprarenal gland.

Nerves.—The Diaphragma is supplied by the phrenic and lower intercostal nerves.

Actions.—The Diaphragma is the principal muscle of inspiration, and presents the form of a dome concave toward the abdomen. The central part of the dome is tendinous, and the pericardium is attached to its upper surface; the circumference is muscular. During inspiration the lowest ribs are fixed, and from these and the crura the muscular fibres contract and draw downward and forward the central tendon with the attached pericardium. In this movement the curvature of the Diaphragma is scarcely altered, the dome moving downward nearly parallel to its original position and pushing before it the abdominal viscera. The descent of the abdominal viscera is permitted by the elasticity of the abdominal wall, but the limit of this is soon reached. The central tendon applied to the abdominal viscera then becomes a fixed point for the action of the Diaphragma, the effect of which is to elevate the lower ribs and through them to push forward the body of the sternum and the upper ribs. The right cupola of the Diaphragma, lying on the liver, has a greater resistance to overcome than the left, which lies over the stomach, but to compensate for this the right crus and the fibres of the right side generally are stronger than those of the left.

In all expulsive acts the Diaphragma is called into action to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and previous to the expulsion of urine or feces, or of the fetus from the uterus, a deep inspiration takes place. The height of the Diaphragma is constantly varying during respiration; it also varies with the

degree of distension of the stomach and intestines and with the size of the liver. After a forced expiration the right cupola is on a level in front with the fourth costal cartilage, at the side with the fifth, sixth, and seventh ribs, and behind with the eighth rib; the left cupola is a little lower than the right. Halls Dally¹ states that the absolute range of movement between deep inspiration and deep expiration averages in the male and female 30 mm. on the right side and 28 mm. on the left; in quiet respiration the average movement is 12.5 mm. on the right side and 12 mm. on the left.

Skiagraphy shows that the height of the Diaphragma in the thorax varies considerably with the position of the body. It stands highest when the body is horizontal and the patient on his back, and in this position it performs the largest respiratory excursions with normal breathing. When the body is erect the dome of the Diaphragma falls, and its respiratory movements become smaller. The dome falls still lower when the sitting posture is assumed, and in this position its respiratory excursions are smallest. These facts may, perhaps, explain why it is that patients suffering from severe dyspnoea are most comfortable and least short of breath when they sit up. When the body is horizontal and the patient on his side, the two halves of the Diaphragma do not behave alike. The uppermost half sinks to a level lower even than when the patient sits, and moves little with respiration; the lower half rises higher in the thorax than it does when the patient is supine, and its respiratory excursions are much increased. In unilateral disease of the pleura or lungs analogous interference with the position or movement of the diaphragma can generally be observed skiagraphically.

It appears that the position of the Diaphragma in the thorax depends upon three main factors, viz.: (1) the elastic retraction of the lung tissue, tending to pull it upward; (2) the pressure exerted on its under surface by the viscera; this naturally tends to be a negative pressure, or downward suction, when the patient sits or stands, and positive, or an upward pressure, when he lies (3) the intra-abdominal tension due to the abdominal muscles. These are in a state of contraction in the standing position and not in the sitting; hence the Diaphragma, when the patient stands, is pushed up higher than when he sits.

The Intercostales interni and externi have probably no action in moving the ribs. They contract simultaneously and form strong elastic supports which prevent the intercostal spaces being pushed out or drawn in during respiration. The anterior portions of the Intercostales interni probably have an additional function in keeping the sternocostal and interchondral joint surfaces in apposition, the posterior parts of the Intercostales externi performing a similar function for the costovertebral articulations. The Levatores costarum being inserted near the fulcrum of the ribs can have little action on the ribs; they act as rotators and lateral flexors of the vertebral column. The Transversus thoracis draws down the costal cartilages, and is therefore a muscle of expiration.

The Serrati are respiratory muscles. The Serratus posterior superior elevates the ribs and is therefore an inspiratory muscle. The Serratus posterior inferior draws the lower ribs downward and backward, and thus elongates the thorax; it also fixes the lower ribs, thus assisting the inspiratory action of the Diaphragma and resisting the tendency it has to draw the lower ribs upward and forward. It must therefore be regarded as a muscle of inspiration.

Mechanism of Respiration.—The respiratory movements must be examined during (a) quiet respiration, and (b) deep respiration.

Quiet Respiration.—The first and second pairs of ribs are fixed by the resistance of the cervical structures; the last pair, and through it the eleventh, by the Quadratus lumborum. The other ribs are elevated, so that the first two intercostal spaces are diminished while the others are increased in width. It has already been shown (p. 401) that elevation of the third, fourth, fifth, and sixth ribs leads to an increase in the antero-posterior and transverse diameters of the thorax; the vertical diameter is increased by the descent of the diaphragmatic dome so that the lungs are expanded in all directions except backward and upward. Elevation of the eighth, ninth, and tenth ribs is accompanied by a lateral and backward movement, leading to an increase in the transverse diameter of the upper part of the abdomen; the elasticity of the anterior abdominal wall allows a slight increase in the antero-posterior diameter of this part, and in this way the decrease in the vertical diameter of the abdomen is compensated and space provided for its displaced viscera. Expiration is effected by the elastic recoil of its walls and by the action of the abdominal muscles, which push back the viscera displaced downward by the Diaphragma.

Deep Respiration.—All the movements of quiet respiration are here carried out, but to a greater extent. In deep inspiration the shoulders and the vertebral borders of the scapulae are fixed and the limb muscles, Trapezius, Serratus anterior, Pectorales, and Latissimus dorsi, are called into play. The Scaleni are in strong action, and the Sternocleidomastoidei also assist when the head is fixed by drawing up the sternum and by fixing the clavicles. The first rib is therefore no longer stationary, but, with the sternum, is raised; with it all the other ribs except the last are raised to a higher level. In conjunction with the increased descent of the Diaphragma this provides for a considerable augmentation of all the thoracic diameters. The anterior abdomi-

MYOLOGY

that the umbilicus is drawn upward and backward, but this more powerful influence on the lower ribs; the transverse diameter is greatly increased and the subcostal angle opened out. *e. g.*, the *Serrati posteriores superiores* and the *Sacrospinales* brought into action; the thoracic curve of the vertebral column whole column, above the lower lumbar vertebrae, drawn back—posterior diameters of the thorax and upper part of the abdomen.

Deep expiration is effected by the recoil of the walls and by the contraction of the muscles of the abdominal wall, and the *Serrati posteriores inferiores*.

The following figures are representing the average changes which occur during expiration. The manubrium sterni moves 30 mm. in an upward direction; the width of the subcostal angle, at a level of 30 mm. below the sternum and the xiphoid process, is increased by 26 mm. and drawn upward for a distance of 13 mm.

MUSCLES AND FASCIAE OF THE ABDOMEN.

The abdominal muscles may be divided into two groups: (1) the **anterior muscles**.

Anterior Muscles of the Abdomen.

are:

Transversus.

Rectus.

Pyramidalis.

To dissect the abdominal muscles, make a vertical incision from the pubis to the umbilicus; a second incision from the umbilicus obliquely upward to the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outward to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outward, in the line of direction of the muscle fibres. If necessary, the abdominal muscles may be made tense by inflating the peritoneal cavity through the umbilicus.

The Superficial Fascia.—The superficial fascia of the abdomen consists, over the greater part of the abdominal wall, of a single layer containing a variable amount of fat; but near the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymph glands.

The superficial layer (*fascia of Camper*) is thick, areolar in texture, and contains in its meshes a varying quantity of adipose tissue. Below, it passes over the inguinal ligament, and is continuous with the superficial fascia of the thigh. In the male, Camper's fascia is continued over the penis and outer surface of the spermatic cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its characteristics, becoming thinner, and of a pale reddish color, and in the scrotum it contains many involuntary muscular fibres. From the scrotum it passes into continuity with the superficial fascia of the

perineum. In the female, Camper's fascia is continued from the abdomen into the labia majora.

The **deep layer** (*fascia of Scarpa*) is thinner and more membranous in character than the superficial, and contains a considerable quantity of yellow elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of the *Obliquus externus abdominis*, but in the middle line it is more intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on to the dorsum of the penis, forming the fundiform ligament; above, it is continuous with the superficial fascia over the rest of the trunk; below and laterally, it blends with the fascia lata of the thigh a little below the inguinal ligament; medially and below, it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward into continuity with the deep layer of the superficial fascia of the perineum (*fascia of Colles*). In the female, it is continued into the labia majora and thence to the fascia of Colles.

The **Obliquus externus abdominis** (*External or descending oblique muscle*) (Fig. 500), situated on the lateral and anterior parts of the abdomen, is the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall of the abdomen. It *arises*, by eight fleshy digitations, from the external surfaces and inferior borders of the lower eight ribs; these digitations are arranged in an oblique line which runs downward and backward, the upper ones being attached close to the cartilages of the corresponding ribs, the lowest to the apex of the cartilage of the last rib, the intermediate ones to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downward, and are received between corresponding processes of the *Serratus anterior*; the three lower ones diminish in size from above downward and receive between them corresponding processes from the *Latissimus dorsi*. From these attachments the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downward, and are inserted into the anterior half of the outer lip of the iliac crest; the middle and upper fibres, directed downward and forward, end in an aponeurosis, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior iliac spine.

The **aponeurosis of the Obliquus externus abdominis** is a thin but strong membranous structure, the fibres of which are directed downward and medialward. It is joined with that of the opposite muscle along the middle line, and covers the whole of the front of the abdomen; *above*, it is covered by and gives origin to the lower fibres of the *Pectoralis major*; *below*, its fibres are closely aggregated together, and extend obliquely across from the anterior superior iliac spine to the pubic tubercle and the pectineal line. In the middle line, it interlaces with the aponeurosis of the opposite muscle, forming the **linea alba**, which extends from the xiphoid process to the symphysis pubis.

That portion of the aponeurosis which extends between the anterior superior iliac spine and the pubic tubercle is a thick band, folded inward, and continuous below with the fascia lata; it is called the **inguinal ligament**. The portion which is reflected from the inguinal ligament at the pubic tubercle is attached to the pectineal line and is called the **lacunar ligament**. From the point of attachment of the latter to the pectineal line, a few fibres pass upward and medialward, behind the medial crus of the subcutaneous inguinal ring, to the linea alba; they diverge as they ascend, and form a thin triangular fibrous band which is called the **reflected inguinal ligament**.

In the aponeurosis of the *Obliquus externus*, immediately above the crest of the pubis, is a triangular opening, the **subcutaneous inguinal ring**, formed by a separation of the fibres of the aponeurosis in this situation.

The following structures require further description, viz., the **subcutaneous**

inguinal ring, the intercrural fibres and fascia, and the inguinal, lacunar, and reflected inguinal ligaments.

The Subcutaneous Inguinal Ring (*annulus inguinalis subcutaneus; external abdominal ring*) (Fig. 501).—The subcutaneous inguinal ring is an interval in the aponeurosis of the Obliquus externus, just above and lateral to the crest of the pubis. The aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures

Subcutaneous
inguinal ring
Lacunar
ligament

FIG. 500.—The Obliquus externus abdominis.

from base to apex about 2.5 cm., and transversely about 1.25 cm. It is bounded *below* by the crest of the pubis; on either *side* by the margins of the opening in the aponeurosis, which are called the **crura of the ring**; and *above*, by a series of curved intercrural fibres. The **inferior crus** (*external pillar*) is the stronger and is formed by that portion of the inguinal ligament which is inserted into the pubic tubercle; it is curved so as to form a kind of groove, upon which, in the male, the spermatic cord rests. The **superior crus** (*internal pillar*) is a broad, thin, flat band, attached to the front of the symphysis pubis and interlacing with its fellow of the opposite side.

The subcutaneous inguinal ring gives passage to the spermatic cord and ilio-inguinal nerve in the male, and to the round ligament of the uterus and the ilioinguinal nerve in the female; it is much larger in men than in women, on account of the large size of the spermatic cord.

The Intercrural Fibres (*fibrae intercrurales; intercolumnar fibres*).—The intercrural fibres are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the Obliquus externus, describing curves with the convexities downward. They have received their name from stretching across between the two crura of the subcutaneous inguinal ring, and they are much thicker and stronger

*Superficial
circumflex*

*subcutaneous inguinal
ring*

FIG. 501.—The subcutaneous inguinal ring.

at the inferior crus, where they are connected to the inguinal ligament, than superiorly, where they are inserted into the linea alba. The intercrural fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the crura from one another; they are more strongly developed in the male than in the female.

As they pass across the subcutaneous inguinal ring, they are connected together by delicate fibrous tissue, forming a fascia, called the **intercrural fascia**. This intercrural fascia is continued down as a tubular prolongation around the spermatic cord and testis, and encloses them in a sheath; hence it is also called the **external spermatic fascia**. The subcutaneous inguinal ring is seen as a distinct aperture only after the intercrural fascia has been removed.

The Inguinal Ligament (*ligamentum inguinale [Pouparti]; Poupart's ligament*) (Fig. 502).—The inguinal ligament is the lower border of the aponeurosis of the

Obliquus externus, and extends from the anterior superior iliac spine to the pubic tubercle. From this latter point it is reflected backward and lateralward to be attached to the pectineal line for about 1.25 cm., forming the lacunar ligament. Its general direction is convex downward toward the thigh, where it is continuous with the fascia lata. Its lateral half is rounded, and oblique in direction; its medial half gradually widens at its attachment to the pubis, is more horizontal in direction, and lies beneath the spermatic cord.

The Lacunar Ligament (*ligamentum lacunare* [Gimbernat]; *Gimbernat's ligament*) (Fig. 502).—The lacunar ligament is that part of the aponeurosis of the *Obliquus externus* which is reflected backward and lateralward, and is attached to the pectineal line. It is about 1.25 cm. long, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base

*Symphysis
pubis*

FIG. 502.—The inguinal and lacunar ligaments.

directed lateralward. Its base is concave, thin, and sharp, and forms the medial boundary of the femoral ring. Its apex corresponds to the pubic tubercle. Its posterior margin is attached to the pectineal line, and is continuous with the pectineal fascia. Its anterior margin is attached to the inguinal ligament. Its surfaces are directed upward and downward.

The Reflected Inguinal Ligament (*ligamentum inguinale reflexum* [Collesi]; *triangular fascia*).—The reflected inguinal ligament is a layer of tendinous fibres of a triangular shape, formed by an expansion from the lacunar ligament and the inferior crus of the subcutaneous inguinal ring. It passes medialward behind the spermatic cord, and expands into a somewhat fan-shaped band, lying behind the superior crus of the subcutaneous inguinal ring, and in front of the inguinal aponeurotic falx, and interlaces with the ligament of the other side of the linea alba.

Ligament of Cooper.—This is a strong fibrous band, which was first described by Sir Astley Cooper. It extends lateralward from the base of the lacunar ligament (Fig. 502) along the pectineal line, to which it is attached. It is strengthened by the pectineal fascia, and by a lateral expansion from the lower attachment of the linea alba (*admiriculum lineae albae*)

Dissection.—Detach the Obliquus externus abdominis by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then separate the muscle carefully from the Obliquus internus abdominis, which lies beneath, and turn it toward the opposite side.

The **Obliquus internus abdominis** (*Internal or ascending oblique muscle*) (Fig. 503), thinner and smaller than the Obliquus externus, beneath which it lies, is of an irregularly quadrilateral form, and situated at the lateral and anterior parts of the abdomen. It *arises*, by fleshy fibres, from the lateral half of the grooved upper surface of the inguinal ligament, from the anterior two-thirds of the middle lip of the iliac crest, and from the posterior lamella of the lumbodorsal fascia. From this origin the fibres diverge; those from the inguinal ligament, few in number

Inguinal aponeurotic falx

FIG. 503.—The Obliquus internus abdominis.

and paler in color than the rest, arch downward and medialward across the spermatic cord in the male and the round ligament of the uterus in the female, and, becoming tendinous, are *inserted*, conjointly with those of the Transversus, into the crest of the pubis and medial part of the pectineal line behind the lacunar ligament, forming what is known as the **inguinal aponeurotic falx**. Those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus abdominis to be inserted into the linea alba. Those arising from the middle third of the iliac origin run obliquely upward and medialward, and end in an aponeurosis; this divides at the lateral border of the Rectus into two lamellæ, which are continued forward, one in front of and the other behind this muscle, to the linea alba:

the posterior lamella has an attachment to the cartilages of the seventh, eighth, and ninth ribs. The most posterior fibres pass almost vertically upward, to be inserted into the inferior borders of the cartilages of the three lower ribs, being continuous with the *Intercostales interni*.

The **Cremaster** (Fig. 504) is a thin muscular layer, composed of a number of fasciculi which *arise* from the middle of the inguinal ligament where its fibres are continuous with those of the *Obliquus internus* and also occasionally with the *Transversus*. It passes along the lateral side of the spermatic cord, descends with it through the subcutaneous inguinal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. At the upper part of the cord the loops are short, but they become in succession longer and longer, the longest reaching down as low as the testis, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the **cremasteric fascia**. The fibres ascend along the medial side of the cord, and are inserted by a small pointed tendon into the tubercle and crest of the pubis and into the front of the sheath of the *Rectus abdominis*.

FIG. 504.—The Cremaster.

Dissection.—Detach the *Obliquus internus abdominis* in order to expose the *Transversus abdominis* beneath. This may be effected by dividing the muscle, *above*, at its attachment to the ribs; *below*, at its connection with the inguinal ligament and the crest of the ilium;

and *behind*, by a vertical incision extending from the last rib to the crest of the ilium. The muscle should previously be made tense by drawing upon it with the fingers of the left hand, and if its division be carefully effected, the cellular interval between it and the *Transversus abdominis*, as well as the direction of the fibres of the latter muscle, will afford a clear guide to their separation; along the crest of the ilium the circumflex iliac vessels are interposed between them, and form an important guide in separating them. The muscle should then be thrown inward toward the linea alba.

The ***Transversus abdominis*** (*Transversalis muscle*) (Fig. 505), so called from the direction of its fibres, is the most internal of the flat muscles of the abdomen, being placed immediately beneath the *Obliquus internus*. It *arises*, by fleshy fibres, from the lateral third of the inguinal ligament, from the anterior three-fourths of the inner lip of the iliac crest, from the inner surfaces of the cartilages of the lower six ribs, interdigitating with the *Diaphragma*, and from the *lumbodorsal fascia*. The muscle ends in front in a broad aponeurosis, the lower fibres of which curve downward and medialward, and are *inserted*, together with those of the *Obliquus internus*, into the crest of the pubis and pectineal line, forming the inguinal aponeurotic falx. Throughout the rest of its extent the aponeurosis passes horizontally to the middle line, and is inserted into the linea alba; its upper three-fourths lie behind the *Rectus* and blend with the posterior lamella of the aponeurosis of the *Obliquus internus*; its lower fourth is in front of the *Rectus*.

The **inguinal aponeurotic falx** (*falx aponeurotica inguinalis*; *conjoined tendon of Internal oblique and Transversalis muscle*) of the Obliquus internus and Transversus is mainly formed by the lower part of the tendon of the Transversus, and is inserted into the crest of the pubis and pectineal line immediately behind the subcutaneous inguinal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Lateral to the falx is a ligamentous band con-

Tendinous inscriptions

Lineæ

FIG. 505.—The Transversus abdominis, Rectus abdominis, and Pyramidalis.

nected with the lower margin of the Transversus and extending down behind the inferior epigastric artery to the superior ramus of the pubis; it is termed the **interfoveolar ligament of Hesselbach** (Fig. 506) and sometimes contains a few muscular fibres.

Dissection.—To expose the Rectus abdominis muscle, open its sheath by a vertical incision extending from the costal arch to the pubis, and then reflect the two portions from the surface of the muscle, which is easily done, excepting at the lineae transversae, where so close an adhesion exists that the greatest care is requisite in separating them. Now raise the outer edge

of the muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the centre, and turning its lower part downward, the point where the posterior wall of the sheath terminates in a thin curved margin will be seen.

The **Rectus abdominis** (Fig. 505) is a long flat muscle, which extends along the whole length of the front of the abdomen, and is separated from its fellow of the opposite side by the linea alba. It is much broader, but thinner, above than below, and *arises* by two tendons; the lateral or larger is attached to the crest of the pubis, the medial interlaces with its fellow of the opposite side, and is connected with the ligaments covering the front of the symphysis pubis. The muscle is *inserted* by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs. The upper portion, attached principally to the cartilage of the fifth rib, usually has some fibres of insertion into the anterior extremity of the rib itself. Some fibres are occasionally connected with the costoxiphoid ligaments, and the side of the xiphoid process.

FIG. 506.—The interfoveolar ligament, seen from in front. (Modified from Braune.)

The Rectus is crossed by fibrous bands, three in number, which are named the **tendinous inscriptions**; one is usually situated opposite the umbilicus, one at the extremity of the xiphoid process, and the third about midway between the xiphoid process and the umbilicus. These inscriptions pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance and may pass only halfway across it; they are intimately adherent in front to the sheath of the muscle. Sometimes one or two additional inscriptions, generally incomplete, are present below the umbilicus.

The Rectus is enclosed in a sheath (Fig. 507) formed by the aponeuroses of the Obliqui and Transversus, which are arranged in the following manner. At the lateral margin of the Rectus, the aponeurosis of the Obliquus internus divides into two lamellæ, one of which passes in front of the Rectus, blending with the aponeurosis of the Obliquus externus, the other, behind it, blending with the aponeurosis of the Transversus, and these, joining again at the medial border of the Rectus, are inserted into the linea alba. This arrangement of the aponeurosis exists from the costal margin to midway between the umbilicus and symphysis pubis, where

the posterior wall of the sheath ends in a thin curved margin, the *linea semicircularis*, the concavity of which is directed downward: below this level the aponeuroses of all three muscles pass in front of the Rectus. The Rectus, in the situation where its sheath is deficient below, is separated from the peritoneum by the transversalis fascia (Fig. 508). Since the tendons of the Obliquus internus and Transversus only reach as high as the costal margin, it follows that above this level the sheath of the Rectus is deficient behind, the muscle resting directly on the cartilages of the ribs, and being covered merely by the tendon of the Obliquus externus.

FIG. 507.—Diagram of sheath of Rectus.

The *Pyramidalis* (Fig. 505) is a small triangular muscle, placed at the lower part of the abdomen, in front of the Rectus, and contained in the sheath of that muscle. It arises by tendinous fibres from the front of the pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upward, diminishing in size as it ascends, and ends by a pointed extremity which is inserted into the linea alba, midway between the umbilicus and pubis. This muscle may be wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it is double on one side, and the muscles of the two sides are sometimes of unequal size. It may extend higher than the level stated.

FIG. 508.—Diagram of a transverse section through the anterior abdominal wall, below the linea semicircularis.

Besides the Rectus and Pyramidalis, the sheath of the Rectus contains the superior and inferior epigastric arteries, and the lower intercostal nerves.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Obliquus internus and Transversus also receive filaments from the anterior branch of the iliohypogastric and sometimes from the ilioinguinal. The Cremaster is supplied by the external spermatic branch of the genitofemoral and the Pyramidalis usually by the twelfth thoracic.

The Linea Alba.—The linea alba is a tendinous raphé in the middle line of the abdomen, stretching between the xiphoid process and the symphysis pubis. It is placed between the medial borders of the Recti, and is formed by the blending of the aponeuroses of the Obliqui and Transversus. It is narrow below, corresponding to the linear interval existing between the Recti; but broader above, where these muscles diverge from one another. At its lower end the linea alba has a double attachment—its superficial fibres passing in front of the medial heads of the Recti to the symphysis pubis, while its deeper fibres form a triangular lamella, attached behind the Recti to the posterior lip of the crest of the pubis, and named the *admiriculum lineae albae*. It presents apertures for the passage of vessels and nerves; the umbilicus, which in the fetus is as an aperture and transmits the umbilical vessels, is closed in the adult.

The Lineae Semilunares.—The lineae semilunares are two curved tendinous lines placed one on either side of the linea alba. Each corresponds with the lateral border of the Rectus, extends from the cartilage of the ninth rib to the pubic tubercle, and is formed by the aponeurosis of the Obliquus internus at its line of division to enclose the Rectus, reinforced in front by that of the Obliquus externus, and behind by that of the Transversus.

Actions.—When the pelvis and thorax are fixed, the abdominal muscles compress the abdominal viscera by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the Diaphragma. By these means assistance is given in expelling the feces from the rectum, the urine from the bladder, the fetus from the uterus, and the contents of the stomach in vomiting.

If the pelvis and vertebral column be fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone be fixed, the thorax is bent directly forward, when the muscles of both sides act; when the muscles of only one side contract, the trunk is bent toward that side and rotated toward the opposite side.

If the thorax be fixed, the muscles, acting together, draw the pelvis upward, as in climbing; or, acting singly, they draw the pelvis upward, and bend the vertebral column to one side or the other. The Recti, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The Transversalis Fascia.—The transversalis fascia is a thin aponeurotic membrane which lies between the inner surface of the Transversus and the extraperitoneal fat. It forms part of the general layer of fascia lining the abdominal parietes, and is directly continuous with the iliac and pelvic fasciæ. In the inguinal region, the transversalis fascia is thick and dense in structure and is joined by fibres from the aponeurosis of the Transversus, but it becomes thin as it ascends to the Diaphragma, and blends with the fascia covering the under surface of this muscle. *Behind*, it is lost in the fat which covers the posterior surfaces of the kidneys. *Below*, it has the following attachments: *posteriorly*, to the whole length of the iliac crest, between the attachments of the Transversus and Iliacus; between the anterior superior iliac spine and the femoral vessels it is connected to the posterior margin of the inguinal ligament, and is there continuous with the iliac fascia. Medial to the femoral vessels it is thin and attached to the pubis and pectineal line, behind the inguinal aponeurotic falx, with which it is united; it descends in front of the femoral vessels to form the anterior wall of the femoral sheath. Beneath the inguinal ligament it is strengthened by a band of fibrous tissue, which is only loosely connected to the ligament, and is specialized as the **deep crural arch**. The spermatic cord in the male and the round ligament of the uterus in the female pass through the transversalis fascia at a spot called the **abdominal inguinal ring**. This opening is not visible externally, since the transversalis fascia is prolonged on these structures as the infundibuliform fascia.

The Abdominal Inguinal Ring (*annulus inguinalis abdominis; interna, or deep abdominal ring*).—The abdominal inguinal ring is situated in the transversalis fascia, midway between the anterior superior iliac spine and the symphysis pubis, and about 1.25 cm. above the inguinal ligament (Fig. 509). It is of an oval form, the long axis of the oval being vertical; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded, *above* and *laterally*, by the arched lower margin of the Transversus; *below* and *medially*, by the inferior epigastric vessels. It transmits the spermatic cord in the male and the round ligament of the uterus in the female. From its circumference a thin funnel-shaped membrane, the **infundibuliform fascia**, is continued around the cord and testis, enclosing them in a distinct covering.

The Inguinal Canal (*canalis inguinalis; spermatic canal*).—The inguinal canal contains the spermatic cord and the ilioinguinal nerve in the male, and the round ligament of the uterus and the ilioinguinal nerve in the female. It is an oblique canal about 4 cm. long, slanting downward and medialward, and placed parallel with and a little above the inguinal ligament; it extends from the abdominal inguinal ring to the subcutaneous inguinal ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the Obliquus externus throughout its whole length, and by the Obliquus internus in its lateral third; *behind*, by the reflected inguinal ligament, the inguinal aponeurotic falx, the transversalis fascia, the extraperitoneal connective tissue and the peritoneum; *above*,

by the arched fibres of *Obliquus internus* and *Transversus abdominis*; *below*, by the union of the *transversalis fascia* with the inguinal ligament, and at its medial end by the lacunar ligament.

Extraperitoneal Connective Tissue.—Between the inner surface of the general layer of the fascia which lines the interior of the abdominal and pelvic cavities, and the peritoneum, there is a considerable amount of connective tissue, termed the **extraperitoneal or subperitoneal connective tissue**.

The **parietal portion** lines the cavity in varying quantities in different situations. It is especially abundant on the posterior wall of the abdomen, and particularly around the kidneys, where it contains much fat. On the anterior wall of the abdomen, except in the pubic region, and on the lateral wall above the iliac crest, it is scanty, and here the *transversalis fascia* is more closely connected with the peritoneum. There is a considerable amount of extraperitoneal connective tissue in the pelvis.

*Abdominal inguin
ring*

Inf. epigastric arte

FIG. 509.—The abdominal inguinal ring.

The **visceral portion** follows the course of the branches of the abdominal aorta between the layers of the mesenterics and other folds of peritoneum which connect the various viscera to the abdominal wall. The two portions are directly continuous with each other.

The Deep Crural Arch.—Curving over the external iliac vessels, at the spot where they become femoral, on the abdominal side of the inguinal ligaments and loosely connected with it, is a thickened band of fibres called the deep crural arch. It is apparently a thickening of the *transversalis fascia* joined laterally to the centre of the lower margin of the inguinal ligament, and arching across the front of the femoral sheath to be inserted by a broad attachment into the pubic tubercle and pectineal line, behind the inguinal aponeurotic falx. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting.

2. The Posterior Muscles of the Abdomen.

Psoas major.

Iliacus.

Psoas minor.

Quadratus lumborum.

The Psoas major, the Psoas minor, and the Iliacus, with the fasciæ covering them, will be described with the muscles of the lower extremity (see page 559).

The Fascia Covering the Quadratus Lumborum.—This is a thin layer attached, *medially*, to the bases of the transverse processes of the lumbar vertebræ; *below*, to the iliolumbar ligament; *above*, to the apex and lower border of the last rib. The upper margin of this fascia, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the lateral lumbocostal arch (page 495). Laterally, it blends with the lumbodorsal fascia, the anterior layer of which intervenes between the Quadratus lumborum and the Sacrospinalis.

The **Quadratus lumborum** (Fig. 495, page 487) is irregularly quadrilateral in shape, and broader below than above. It *arises* by aponeurotic fibres from the iliolumbar ligament and the adjacent portion of the iliac crest for about 5 cm., and is *inserted* into the lower border of the last rib for about half its length, and by four small tendons into the apices of the transverse processes of the upper four lumbar vertebræ. Occasionally a second portion of this muscle is found in front of the preceding. It *arises* from the upper borders of the transverse processes of the lower three or four lumbar vertebræ, and is *inserted* into the lower margin of the last rib. In front of the Quadratus lumborum are the colon, the kidney, the Psoas major and minor, and the Diaphragma; between the fascia and the muscle are the twelfth thoracic, ilioinguinal, and iliohypogastric nerves.

Nerve Supply.—The twelfth thoracic and first and second lumbar nerves supply this muscle.

Actions.—The Quadratus lumborum draws down the last rib, and acts as a muscle of inspiration by helping to fix the origin of the Diaphragma. If the thorax and vertebral column are fixed, it may act upon the pelvis, raising it toward its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

V. THE MUSCLES AND FASCIÆ OF THE PELVIS.

Obturator internus.

Levator ani.

Piriformis.

Coccygeus.

The muscles within the pelvis may be divided into two groups: (1) the Obturator internus and the Piriformis, which are muscles of the lower extremity, and will be described with these (pages 571 and 572); (2) the Levator ani and the Coccygeus, which together form the **pelvic diaphragm** and are associated with the pelvic viscera. The classification of the two groups under a common heading is convenient in connection with the fasciæ investing the muscles. These fasciæ are closely related to one another and to the deep fascia of the perineum, and in addition have special connections with the fibrous coverings of the pelvic viscera; it is customary therefore to describe them together under the term **pelvic fascia**.

Pelvic Fascia.—The fascia of the pelvis may be resolved into: (a) the facial sheaths of the Obturator internus, Piriformis, and pelvic diaphragm; (b) the fascia associated with the pelvic viscera.

The **fascia of the Obturator internus** covers the pelvic surface of, and is attached around the margin of the origin of, the muscle. *Above*, it is loosely connected to the back part of the arcuate line, and here it is continuous with the iliac fascia. In front of this, as it follows the line of origin of the Obturator internus, it gradually separates from the iliac fascia and the continuity between the two is retained only through the periosteum. It arches beneath the obturator vessels and nerve, completing the obturator canal, and at the front of the pelvis is attached to the back

of the superior ramus of the pubis. *Below*, the obturator fascia is attached to the falciform process of the sacrotuberous ligament and to the pubic arch, where it becomes continuous with the superior fascia of the urogenital diaphragm. *Behind*, it is prolonged into the gluteal region.

The internal pudendal vessels and pudendal nerve cross the pelvic surface of the Obturator internus and are enclosed in a special canal—**Alcock's canal**—formed by the obturator fascia.

The **fascia of the Piriformis** is very thin and is attached to the front of the sacrum and the sides of the greater sciatic foramen; it is prolonged on the muscle into the gluteal region. At its sacral attachment around the margins of the anterior sacral foramina it comes into intimate association with and ensheathes the nerves emerging from these foramina. Hence the sacral nerves are frequently described as lying behind the fascia. The internal iliac vessels and their branches, on the other hand, lie in the subperitoneal tissue in front of the fascia, and the branches to the gluteal region emerge in special sheaths of this tissue, above and below the Piriformis muscle.

Diaphragmatic
part of pelvic
fascia

Tendi

FIG. 510.—Coronal section of pelvis, showing arrangement of fasciæ. Viewed from behind. (Diagrammatic.)

The **diaphragmatic part of the pelvic fascia** (Fig. 510) covers both surfaces of the Levatores ani. The inferior layer is known as the **anal fascia**; it is attached above to the obturator fascia along the line of origin of the Levator ani, while below it is continuous with the superior fascia of the urogenital diaphragm, and with the fascia on the Sphincter ani internus. The layer covering the upper surface of the pelvic diaphragm follows, above, the line of origin of the Levator ani and is therefore somewhat variable. In front it is attached to the back of the symphysis pubis about 2 cm. above its lower border. It can then be traced laterally across the back of the superior ramus of the pubis for a distance of about 1.25 cm., when it reaches the obturator fascia. It is attached to this fascia along a line which pursues a somewhat irregular course to the spine of the ischium. The irregularity of this line is due to the fact that the origin of the Levator ani, which in lower forms is from the pelvic brim, is in man lower down, on the obturator fascia. Tendinous fibres of origin of the muscle are therefore often found extending up toward, and in some cases reaching, the pelvic brim, and on these the fascia is carried.

It will be evident that the fascia covering that part of the Obturator internus which lies above the origin of the Levator ani is a composite fascia and includes the following: (a) the obturator fascia; (b) the fascia of the Levator ani; (c) degenerated fibres of origin of the Levator ani.

The lower margin of the fascia covering the upper surface of the pelvic diaphragm is attached along the line of insertion of the Levator ani.

At the level of a line extending from the lower part of the symphysis pubis to the spine of the ischium is a thickened whitish band in this upper layer of the diaphragmatic part of the pelvic fascia. It is termed the **tendinous arch or white line of the pelvic fascia**, and marks the line of attachment of the special fascia (*pars endopelvina fasciae pelvis*) which is associated with the pelvic viscera.

FIG. 511.—Median sagittal section of pelvis, showing arrangement of fasciae.

The **endopelvic part of the pelvic fascia** is continued over the various pelvic viscera (Fig. 511) to form for them fibrous coverings which will be described later (see section on Splanchnology). It is attached to the diaphragmatic part of the pelvic fascia along the tendinous arch, and has been subdivided in accordance with the viscera to which it is related. Thus its anterior part, known as the **vesical layer**, forms the anterior and lateral ligaments of the bladder. Its middle part crosses the floor of the pelvis between the rectum and vesiculae seminales as the **rectovesical layer**; in the female this is perforated by the vagina. Its posterior

portion passes to the side of the rectum; it forms a loose sheath for the rectum, but is firmly attached around the anal canal; this portion is known as the **rectal layer**.

The **Levator ani** (Fig. 512) is a broad, thin muscle, situated on the side of the pelvis. It is attached to the inner surface of the side of the lesser pelvis, and unites with its fellow of the opposite side to form the greater part of the floor of the pelvic cavity. It supports the viscera in this cavity, and surrounds the various structures which pass through it. It *arises*, in front, from the posterior surface of the superior ramus of the pubis lateral to the symphysis; behind, from the inner surface of the spine of the ischium; and between these two points, from the obturator fascia.

Anococcygeal raphe

FIG. 512.—Left Levator ani from within.

Posteriorly, this fascial origin corresponds, more or less closely, with the tendinous arch of the pelvic fascia, but in front, the muscle arises from the fascia at a varying distance above the arch, in some cases reaching nearly as high as the canal for the obturator vessels and nerve. The fibres pass downward and backward to the middle line of the floor of the pelvis; the most posterior are inserted into the side of the last two segments of the coccyx; those placed more anteriorly unite with the muscle of the opposite side, in a median fibrous raphé (**anococcygeal**

raphé), which extends between the coccyx and the margin of the anus. The middle fibres are inserted into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres descend upon the side of the prostate to unite beneath it with the muscle of the opposite side, joining with the fibres of the Sphincter ani externus and Transversus perinaei, at the central tendinous point of the perineum.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate, which it supports as in a sling, it has been described as a distinct muscle, under the name of **Levator prostatae**. In the female the anterior fibres of the Levator ani descend upon the side of the vagina.

Relations.—By its *upper or pelvic surface*, with the diaphragmatic part of the pelvic fascia which separates it from the bladder, prostate, rectum, and peritoneum. By its *lower or perineal surface*, it forms the medial boundary of the ischioanal fossa, and is covered by the inferior layer of the diaphragmatic part of the pelvic fascia (*anal fascia*). Its *posterior border* is free and separated from the Coccygeus by areolar tissue. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, pass from the pelvis.

The Levator ani may be divided into iliococcygeal and pubococcygeal parts.

The *Iliococcygeus* arises from the ischial spine and from the posterior part of the tendinous arch of the pelvic fascia, and is attached to the coccyx and anococcygeal raphé; it is usually thin, and may fail entirely, or be largely replaced by fibrous tissue. An accessory slip at its posterior part is sometimes named the *Iliosacralis*. The *Pubococcygeus* arises from the back of the pubis and from the anterior part of the obturator fascia, and "is directed backward almost horizontally along the side of the anal canal toward the coccyx and sacrum, to which it finds attachment. Between the termination of the vertebral column and the anus, the two Pubococcygei muscles come together and form a thick, fibromuscular layer lying on the raphé formed by the Iliococcygei" (Peter Thompson). The greater part of this muscle is *inserted* into the coccyx and into the last one or two pieces of the sacrum. This insertion into the vertebral column is, however, not admitted by all observers. The fibres which form a sling for the rectum are named the *Puborectalis* or *Sphincter recti*. They arise from the lower part of the symphysis pubis, and from the superior fascia of the urogenital diaphragm. They meet with the corresponding fibres of the opposite side around the lower part of the rectum, and form for it a strong sling.

Nerve Supply.—The Levator ani is supplied by a branch from the fourth sacral nerve and by a branch which is sometimes derived from the perineal, sometimes from the inferior hemorrhoidal division of the pudendal nerve.

The **Coccygeus** (Fig. 512) is situated behind the preceding. It is a triangular plane of muscular and tendinous fibres, *arising* by its apex from the spine of the ischium and sacrospinous ligament, and *inserted* by its base into the margin of the coccyx and into the side of the lowest piece of the sacrum. It assists the Levator ani and Piriformis in closing in the back part of the outlet of the pelvis.

Nerve Supply.—The Coccygeus is supplied by a branch from the fourth and fifth sacral nerves.

Actions.—The Levatores ani constrict the lower end of the rectum and vagina. They elevate and invert the lower end of the rectum after it has been protruded and everted during the expulsion of the feces. They are also muscles of forced expiration. The Coccygei pull forward and support the coccyx, after it has been pressed backward during defecation or parturition. The Levatores ani and Coccygei together form a muscular diaphragm which supports the pelvic viscera.

VI. THE MUSCLES AND FASCIAE OF THE PERINEUM.

The perineum corresponds to the outlet of the pelvis. Its deep boundaries are—in *front*, the pubic arch and the arcuate ligament of the pubis; *behind*, the tip of the coccyx; and on either side the inferior rami of the pubis and ischium, and the sacrotuberous ligament. The space is somewhat lozenge-shaped and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and laterally by the medial side of the thigh. A line drawn transversely across in front of the ischial tuberosities divides the space into two portions. The posterior contains the termination of the anal canal and is known as the **anal region**;

the anterior, which contains the external urogenital organs, is termed the **urogenital region**.

The muscles of the perineum may therefore be divided into two groups:

1. Those of the anal region.
2. Those of the urogenital region: A, In the male; B, In the female.

1. The Muscles of the Anal Region.

Corrugator cutis ani. Sphincter ani externus. Sphincter ani internus.

The Superficial Fascia.—The superficial fascia is very thick, areolar in texture, and contains much fat in its meshes. On either side a pad of fatty tissue extends deeply between the Levator ani and Obturator internus into a space known as the **ischiorectal fossa**.

The Deep Fascia.—The deep fascia forms the lining of the ischiorectal fossa; it comprises the anal fascia, and the portion of obturator fascia below the origin of Levator ani.

FIG. 513.—The perineum. The integument and superficial layer of superficial fascia reflected.

Ischiorectal Fossa (*fossa ischiorectalis*) (Fig. 513).—The fossa is somewhat prismatic in shape, with its base directed to the surface of the perineum, and its apex at the line of meeting of the obturator and anal fasciæ. It is bounded *medially* by the Sphincter ani externus and the anal fascia; *laterally*, by the tuberosity of the ischium and the obturator fascia; *anteriorly*, by the fascia of Colles covering the Transversus perinaei superficialis, and by the inferior fascia of the urogenital diaphragm; *posteriorly*, by the Glutæus maximus and the sacrotuberous ligament. Crossing the space transversely are the inferior hemorrhoidal vessels and nerves; at the back part are the perineal and perforating cutaneous branches of the pudendal plexus; while from the forepart the posterior scrotal (or labial) vessels and nerves emerge. The internal pudendal vessels and pudendal nerve lie in

Alcock's canal on the lateral wall. The fossa is filled with fatty tissue across which numerous fibrous bands extend from side to side.

Applied Anatomy.—Abscess in the ischiorectal fossa commonly occurs; it is most often the result of infection from the bowel, and is especially prone to occur in tuberculous subjects; occasionally it follows perforation by a foreign body which has been swallowed, such as a fish bone. The abscess may bulge at the side of the anus, at the border of *Glutaeus maximus*, or against the rectal wall. There is great pain on defecation. On examining the bowel, fulness on the side of the abscess may be detected. If left to itself the pus will find exit through the skin, or into the rectum between the two Sphincters; and the condition will degenerate into one of the varieties of fistula, owing to the constant pull of the *Sphincter ani externus* preventing closure of the walls of the cavity. These abscesses should be opened at the earliest possible moment, as they tend to track and burrow widely into the soft fat in the fossa, and also in the subcutaneous tissues. An incision should be made tangential to the anus over the region of the ischiorectal fossa, and should then be converted into a T, by making a second incision laterally at right angles to it, so that the wound may be kept open and may heal up from the bottom. Frequently, however, in spite of care, a fistula ensues which requires division of the *Sphincter ani externus* for its cure.

The Corrugator Cutis Ani.—Around the anus is a thin stratum of involuntary muscular fibre, which radiates from the orifice. *Medially* the fibres fade off into the submucous tissue, while *laterally* they blend with the true skin. By its contraction it raises the skin into ridges around the margin of the anus.

The **Sphincter ani externus** (*External sphincter ani*) (Fig 513) is a flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about 8 to 10 cm. in length, from its anterior to its posterior extremity, and is about 2.5 cm. broad opposite the anus. It consists of two strata, superficial and deep. The *superficial*, constituting the main portion of the muscle, arises from a narrow tendinous band, the **anococcygeal raphé**, which stretches from the tip of the coccyx to the posterior margin of the anus; it forms two flattened planes of muscular tissue, which encircle the anus and meet in front to be inserted into the central tendinous point of the perineum, joining with the *Transversus perinaei superficialis*, the *Levator ani*, and the *Bulbocavernosus*. The *deeper portion* forms a complete sphincter to the anal canal. Its fibres surround the canal, closely applied to the *Sphincter ani internus*, and in front blend with the other muscles at the central point of the perineum. In a considerable proportion of cases the fibres decussate in front of the anus, and are continuous with the *Transversi perinaei superficiales*. Posteriorly, they are not attached to the coccyx, but are continuous with those of the opposite side behind the anal canal. The upper edge of the muscle is ill-defined, since fibres are given off from it to join the *Levator ani*.

Nerve Supply.—A branch from the fourth sacral and twigs from the inferior hemorrhoidal branch of the pudendal supply the muscle.

Actions.—The action of this muscle is peculiar. (1) It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle it keeps the anal canal and orifice closed. (2) It can be put into a condition of greater contraction under the influence of the will, so as more firmly to occlude the anal aperture, in expiratory efforts unconnected with defecation. (3) Taking its fixed point at the coccyx, it helps to fix the central point of the perineum, so that the *Bulbocavernosus* may act from this fixed point.

The **Sphincter ani internus** (*Internal sphincter ani*) is a muscular ring which surrounds about 2.5 cm. of the anal canal; its inferior border is in contact with, but quite separate from, the *Sphincter ani externus*. It is about 5 mm. thick, and is formed by an aggregation of the involuntary circular fibres of the intestine. Its lower border is about 6 mm. from the orifice of the anus.

Actions.—Its action is entirely involuntary. It helps the *Sphincter ani externus* to occlude the anal aperture and aids in the expulsion of the feces.

2. A. **The Muscles of the Urogenital Region in the Male** (Fig. 514).

Transversus perinaei superficialis.	Ischiocavernosus.
Bulbocavernosus.	Transversus perinaei profundus.
Sphincter urethrae membranaceae.	

Superficial Fascia.—The superficial fascia of this region consists of two layers, superficial and deep.

FIG. 514.—Muscles of male perineum.

The superficial layer is thick, loose, areolar in texture, and contains in its meshes much adipose tissue, the amount of which varies in different subjects. In *front*, it is continuous with the dartos tunic of the scrotum; *behind*, with the subcutaneous areolar tissue surrounding the anus; and, on *either side*, with the same fascia on the inner sides of the thighs. In the *middle line*, it is adherent to the skin on the raphe, and to the deep layer of the superficial fascia.

The deep layer of superficial fascia (*fascia of Colles*) (Fig. 513) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the region of the penis. It is continuous, in *front*, with the dartos tunic, the deep fascia of the penis, the fascia of the spermatic cord, and Scarpa's fascia upon the

anterior wall of the abdomen; on *either side* it is firmly attached to the margins of the rami of the pubis and ischium, lateral to the crus penis and as far back as the tuberosity of the ischium; *posteriorly*, it curves around the Transversi perinaei superficiales to join the lower margin of the inferior fascia of the urogenital diaphragm. In the *middle line*, it is connected with the superficial fascia and with the median septum of the Bulbocavernosus. This fascia not only covers the muscles in this region, but at its back part sends upward a vertical septum from its deep surface, which separates the posterior portion of the subjacent space into two.

The Central Tendinous Point of the Perineum.—This is a fibrous point in the middle line of the perineum, between the urethra and anus, and about 1.25 cm. in front of the latter. At this point six muscles converge and are attached: viz., the Sphincter ani externus, the Bulbocavernosus, the two Transversi perinaei superficiales, and the anterior fibres of the Levatores ani.

The **Transversus perinaei superficialis** (*Transversus perinaei*; *Superficial transverse perineal muscle*) is a narrow muscular slip, which passes more or less transversely across the perineal space in front of the anus. It *arises* by tendinous fibres from the inner and forepart of the tuberosity of the ischium, and, running medialward, is inserted into the central tendinous point of the perineum, joining in this situation with the muscle of the opposite side, with the Sphincter ani externus behind, and with the Bulbocavernosus in front. In some cases, the fibres of the deeper layer of the Sphincter ani externus decussate in front of the anus and are continued into this muscle. Occasionally it gives off fibres, which join with the Bulbocavernosus of the same side.

Actions.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perineum.

The **Bulbocavernosus** (*Ejaculator urinae*; *Accelerator urinae*) is placed in the middle line of the perineum, in front of the anus. It consists of two symmetrical parts, united along the median line by a tendinous raphé. It *arises* from the central tendinous point of the perineum and from the median raphé in front. Its fibres diverge like the barbs of a quill-pen; the most posterior form a thin layer, which is lost on the inferior fascia of the urogenital diaphragm; the middle fibres encircle the bulb and adjacent parts, of the corpus cavernosum urethrae, and join with the fibres of the opposite side, on the upper part of the corpus cavernosum urethrae, in a strong aponeurosis; the anterior fibres, spread out over the side of the corpus cavernosum penis, to be inserted partly into that body, anterior to the Ischiocavernosus, occasionally extending to the pubis, and partly ending in a tendinous expansion which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and reflecting it from the surface of the corpus cavernosum urethrae.

Actions.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed by Krause to assist in the erection of the corpus cavernosum urethrae, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis by compressing the deep dorsal vein of the penis as they are inserted into, and continuous with, the fascia of the penis.

The **Ischiocavernosus** (*Erector penis*) covers the crus penis. It is an elongated muscle, broader in the middle than at either end, and situated on the lateral boundary of the perineum. It *arises* by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis; and from the rami of the pubis and ischium on either side of the crus. From these points fleshy fibres succeed, and end in an aponeurosis which is *inserted* into the sides and under surface of the crus penis.

Action.—The Ischiocavernosus compresses the crus penis, and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded medially by the Bulbocavernosus, laterally by the Ischiocavernosus, and behind by the Transversus perinaei superficialis; the floor is formed by the inferior fascia of the urogenital diaphragm. Running from behind forward in the space are the posterior scrotal vessels and nerves, and the perineal branch of the posterior femoral cutaneous nerve; the transverse perineal artery courses along its posterior boundary on the Transversus perinaei superficialis.

The Deep Fascia.—The deep fascia of the urogenital region forms an investment for the Transversus perinaei profundus and the Sphincter urethrae membranaceae, but within it lie also the deep vessels and nerves of this part, the whole forming a transverse septum which is known as the **urogenital diaphragm**. From its shape it is usually termed the **triangular ligament**, and is stretched almost horizontally across the pubic arch, so as to close in the front part of the outlet of the pelvis. It consists of two dense membranous laminae (Fig. 515), which are united along their posterior borders, but are separated in front by intervening structures. The superficial of these two layers, the **inferior fascia of the urogenital diaphragm**, is triangular in shape, and about 4 cm. in depth. Its apex is directed forward, and is

 The diagram shows a coronal section of the anterior part of the pelvis. A bracket on the left groups two layers of the urogenital diaphragm, with the label 'Inferior layer' pointing to the lower layer. To the right of this bracket is the label 'Bulbocavernosus'.

FIG. 515.—Coronal section of anterior part of pelvis, through the pubic arch. Seen from in front. (Diagrammatic.)

separated from the arcuate pubic ligament by an oval opening for the transmission of the deep dorsal vein of the penis. Its lateral margins are attached on either side to the inferior rami of the pubis and ischium, above the crus penis. Its base is directed toward the rectum, and connected to the central tendinous point of the perineum. It is continuous with the deep layer of the superficial fascia behind the Transversus perinaei superficialis, and with the inferior layer of the diaphragmatic part of the pelvic fascia. It is perforated, about 2.5 cm. below the symphysis pubis, by the urethra, the aperture for which is circular and about 6 mm. in diameter by the arteries to the bulb and the ducts of the bulbourethral glands close to the urethral orifice; by the deep arteries of the penis, one on either side close to the pubic arch and about halfway along the attached margin of the fascia; by the dorsal arteries and nerves of the penis near the apex of the fascia. Its base is also perforated by the perineal vessels and nerves, while between its apex and the arcuate pubic ligament the deep dorsal vein of the penis passes upward into the pelvis.

If the inferior fascia of the urogenital diaphragm be detached on either side, the following structures will be seen between it and the superior fascia: the deep dorsal vein of the penis; the membranous portion of the urethra; the *Transversus perinaei profundus* and *Sphincter urethrae membranaceae* muscles; the bulbo-urethral glands and their ducts; the pudendal vessels and dorsal nerves of the penis; the arteries and nerves of the urethral bulb, and a plexus of veins.

The *superior fascia of the urogenital diaphragm* is continuous with the obturator fascia and stretches across the pubic arch. If the obturator fascia be traced medially after leaving the Obturator internus muscle, it will be found attached by some of its deeper or anterior fibres to the inner margin of the pubic arch, while its superficial or posterior fibres pass over this attachment to become continuous with the superior fascia of the urogenital diaphragm. Behind, this layer of the fascia is continuous with the inferior fascia and with the fascia of Colles; in front it is continuous with the fascial sheath of the prostate, and is fused with the inferior fascia to form the *transverse ligament of the pelvis*.

The *Transversus perinaei profundus* arises from the inferior rami of the ischium and runs to the median line, where it interlaces in a tendinous raphé with its fellow of the opposite side. It lies in the same plane as the *Sphincter urethrae membranaceae*; formerly the two muscles were described together as the *Constrictor urethrae*.

The *Sphincter urethrae membranaceae* surrounds the whole length of the membranous portion of the urethra, and is enclosed in the fasciæ of the urogenital diaphragm. Its *external* fibres arise from the junction of the inferior rami of the pubis and ischium to the extent of 1.25 to 2 cm., and from the neighboring fasciæ. They arch across the front of the urethra and bulbourethral glands, pass around the urethra, and behind it unite with the muscle of the opposite side, by means of a tendinous raphé. Its *innermost* fibres form a continuous circular investment for the membranous urethra.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the *Bulbocavernosus*, are relaxed, and only come into action at the end of the process to eject the last drops of the fluid.

Nerve Supply.—The perineal branch of the pudendal nerve supplies this group of muscles.

2. B. The Muscles of the Urogenital Region in the Female (Fig. 515).

Transversus perinaei superficialis.

Ischiocavernosus.

Bulbocavernosus.

Transversus perinaei profundus.

Sphincter urethrae membranaceae.

The *Transversus perinaei superficialis* (*Transversus perinaei*; *Superficial transverse perineal muscle*) in the female is a narrow muscular slip, which arises by a small tendon from the inner and forepart of the tuberosity of the ischium, and is inserted into the central tendinous point of the perineum, joining in this situation with the muscle of the opposite side, the *Sphincter ani externus* behind, and the *Bulbocavernosus* in front.

Action.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perineum.

The *Bulbocavernosus* (*Sphincter vaginae*) surrounds the orifice of the vagina. It covers the lateral parts of the vestibular bulbs, and is attached posteriorly to the central tendinous point of the perineum, where it blends with the *Sphincter ani externus*. Its fibres pass forward on either side of the vagina to be inserted into the corpora cavernosa clitoridis, a fasciculus crossing over the body of the organ so as to compress the deep dorsal vein.

Actions.—The *Bulbocavernosus* diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris, compressing the deep dorsal vein during the contraction of the muscle.

The **Ischiocavernosus** (*Erector clitoridis*) is smaller than the corresponding muscle in the male. It covers the unattached surface of the crus clitoridis. It is an elongated muscle, broader at the middle than at either end, and situated on the side of the lateral boundary of the perineum. It *arises* by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis; from the surface of the crus; and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, and end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

Clitoris
/

Urethra

Vagina

Sphincter ani externus

FIG. 516.—Muscles of the female perineum. (Modified from a drawing by Peter Thompson.)

Actions.—The Ischiocavernosus compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The **fascia of the urogenital diaphragm** in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the arcuate pubic ligament. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the *Transversus perinaei superficialis*.

Like the corresponding fascia in the male, it consists of two layers, between which are to be found the following structures: the deep dorsal vein of the clitoris, a portion of the urethra and the Constrictor urethra muscle, the larger vestibular glands and their ducts; the internal pudendal vessels and the dorsal nerves of the clitoris; the arteries and nerves of the bulbi vestibuli, and a plexus of veins.

The **Transversus perinaei profundus** *arises* from the inferior rami of the ischium and runs across to the side of the vagina. The *Sphincter urethrae membranaceae* (*Constrictor urethrae*), like the corresponding muscle on the male, consists of external and internal fibres. The *external* fibres arise on either side from the margin of the

inferior ramus of the pubis. They are directed across the pubic arch in front of the urethra, and pass around it to blend with the muscular fibres of the opposite side, between the urethra and vagina. The *innermost* fibres encircle the lower end of the urethra.

Nerve Supply.—The muscles of this group are supplied by the perineal branch of the pudendal.

THE MUSCLES AND FASCIÆ OF THE UPPER EXTREMITY.

The muscles of the upper extremity are divisible into groups, corresponding with the different regions of the limb.

- | | |
|--|----------------------------|
| I. Muscles Connecting the Upper Extremity to the Vertebral Column. | |
| II. Muscles Connecting the Upper Extremity to the Anterior and Lateral Thoracic Walls. | |
| III. Muscles of the Shoulder. | V. Muscles of the Forearm. |
| IV. Muscles of the Arm. | VI. Muscles of the Hand. |

I. THE MUSCLES CONNECTING THE UPPER EXTREMITY TO THE VERTEBRAL COLUMN.

The muscles of this group are:

- | | |
|-------------------|--------------------|
| Trapezius. | Rhomboideus major. |
| Latissimus dorsi. | Rhomboideus minor. |
| | Levator scapulae. |

Superficial Fascia.—The superficial fascia of the back forms a layer of considerable thickness and strength, and contains a quantity of granular fat. It is continuous with the general superficial fascia.

Deep Fascia.—The deep fascia is a dense fibrous layer, attached above to the superior nuchal line of the occipital bone; in the middle line it is attached to the ligamentum nuchae and supraspinal ligament, and to the spinous processes of all the vertebræ below the seventh cervical; laterally, in the neck it is continuous with the deep cervical fascia; over the shoulder it is attached to the spine of the scapula and to the acromion, and is continued downward over the Deltoideus to the arm; on the thorax it is continuous with the deep fascia of the axilla and chest, and on the abdomen with that covering the abdominal muscles; below, it is attached to the crest of the ilium.

The **Trapezius** (Fig. 517) is a flat, triangular muscle, covering the upper and back part of the neck and shoulders. It *arises* from the external occipital protuberance and the medial third of the superior nuchal line of the occipital bone, from the ligamentum nuchae, the spinous process of the seventh cervical, and the spinous processes of all the thoracic vertebræ, and from the corresponding portion of the supraspinal ligament. From this origin, the superior fibres proceed downward and lateralward, the inferior upward and lateralward, and the middle horizontally; the superior fibres are inserted into the posterior border of the lateral third of the clavicle; the middle fibres into the medial margin of the acromion, and into the superior lip of the posterior border of the spine of the scapula; the inferior fibres converge near the scapula, and end in an aponeurosis, which glides over the smooth triangular surface on the medial end of the spine, to be inserted into a tubercle at the apex of this smooth triangular surface. At its occipital origin, the Trapezius is connected to the bone by a thin fibrous lamina, firmly adherent to the skin. At the middle it is connected to the spinous processes by a broad semi-elliptical aponeurosis, which reaches from the sixth cervical to the third thoracic vertebræ, and forms, with that of the opposite muscle, a tendinous ellipse. The rest of the

FIG. 517.—Muscles connecting the upper extremity to the vertebral column.

muscle arises by numerous short tendinous fibres. The two Trapezius muscles together resemble a trapezium, or diamond-shaped quadrangle: two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the twelfth thoracic vertebra.

The clavicular *insertion* of this muscle varies in extent; it sometimes reaches as far as the middle of the clavicle, and occasionally may blend with the posterior edge of the Sternocleidomastoideus, or overlap it.

The **Latissimus dorsi** (Fig. 517) is a triangular, flat muscle, which covers the lumbar region and the lower half of the thoracic region, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. It *arises* by tendinous fibres from the spinous processes of the lower six thoracic vertebrae and from the posterior layer of the lumbodorsal fascia (see page 486), by which it is attached to the spines of the lumbar and sacral vertebrae, to the supraspinal ligament, and to the posterior part of the crest of the ilium. It also *arises* by muscular fibres from the external lip of the crest of the ilium lateral to the margin of the Sacrospinalis, and from the three or four lower ribs by fleshy digitations, which are interposed between similar processes of the Obliquus abdominis externus (Fig. 500, page 500). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upward, and the lower vertically upward, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and usually receives a few fibres from it. The muscle curves around the lower border of the Teres major, and is twisted upon itself, so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It ends in a quadrilateral tendon, about 7 cm. long, which passes in front of the tendon of the Teres major, and is inserted into the bottom of the intertubercular groove of the humerus; its insertion extends higher on the humerus than that of the tendon of the Pectoralis major. The lower border of its tendon is united with that of the Teres major, the surfaces of the two being separated near their insertions by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. The tendon of the muscle gives off an expansion to the deep fascia of the arm.

A muscular slip, the **axillary arch**, varying from 7 to 10 cm. in length, and from 5 to 15 mm. in breadth, occasionally springs from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coracobrachialis, or the fascia over the Biceps brachii. This axillary arch crosses the axillary artery, just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It is present in about 7 per cent. of subjects and may be easily recognized by the transverse direction of its fibres.

A fibrous slip usually passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps brachii. This is occasionally muscular, and is the representative of the *Dorsoepitrochlearis brachii* of apes.

The lateral margin of the Latissimus dorsi is separated below from the Obliquus externus abdominis by a small triangular interval, the **lumbar triangle of Petit**, the base of which is formed by the iliac crest, and its floor by the Obliquus internus abdominis. Another triangle is situated behind the scapula. It is bounded above by the Trapezius, below by the Latissimus dorsi, and laterally by the vertebral border of the scapula; the floor is partly formed by the Rhomboideus major. If the scapula be drawn forward by folding the arms across the chest, and the trunk bent forward, parts of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation. The space is therefore known as the **triangle of auscultation**.

Nerves.—The Trapezius is supplied by the accessory nerve, and by branches from the third and fourth cervical nerves; the Latissimus dorsi by the sixth, seventh, and eighth cervical nerves through the thoracodorsal (long subscapular) nerve.

of the

The **Rhomboideus major** (Fig. 517) *arises* by tendinous fibres from the spinous processes of the second, third, fourth, and fifth thoracic vertebræ and the supra-spinal ligament, and is *inserted* into a narrow tendinous arch, attached above to the lower part of the triangular surface at the root of the spine of the scapula; below to the inferior angle, the arch being connected to the vertebral border by a thin membrane. When the arch extends, as it occasionally does, only a short distance, the muscular fibres are inserted directly into the scapula.

The **Rhomboideus minor** (Fig. 517) arises from the lower part of the ligamentum Nuchæ and from the spinous processes of the seventh cervical and first thoracic vertebræ. It is *inserted* into the base of the triangular smooth surface at the root of the spine of the scapula, and is usually separated from the Rhomboideus major by a slight interval, but the adjacent margins of the two muscles are occasionally united.

The **Levator scapulae** (*Levator anguli scapulae*) (Fig. 517) is situated at the back and side of the neck. It *arises* by tendinous slips from the transverse processes of the atlas and axis and from the posterior tubercles of the transverse processes of the third and fourth cervical vertebræ. It is *inserted* into the vertebral border of the scapula, between the medial angle and the triangular smooth surface at the root of the spine.

Nerves.—The Rhomboidei are supplied by the dorsal scapular nerve from the fifth cervical; the Levator scapulae by the third and fourth cervical nerves, and frequently by a branch from the dorsal scapular.

Actions.—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachments. When the whole Trapezius is in action it retracts the scapula and braces back the shoulder; if the head be fixed, the upper part of the muscle will elevate the point of the shoulder, as in supporting weights; when the lower fibres contract they assist in depressing the scapula. The middle and lower fibres of the muscle rotate the scapula, causing elevation of the acromion. If the shoulders be fixed, the Trapezii, acting together, will draw the head directly backward; or if only one act, the head is drawn to the corresponding side.

When the Latissimus dorsi acts upon the humerus, it depresses and draws it backward, and at the same time rotates it inward. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm be fixed, the muscle may act in various ways upon the trunk; thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms be fixed, the two muscles may assist the abdominal muscles and Pectorales in suspending and drawing the trunk forward, as in climbing.

If the head be fixed, the Levator scapulae raises the medial angle of the scapula; if the shoulder be fixed, the muscle inclines the neck to the corresponding side and rotates it in the same direction. The Rhomboidei carry the inferior angle backward and upward, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboideus major acting especially on the inferior angle of the scapula, through the tendinous arch by which it is inserted. The Rhomboidei, acting together with the middle and inferior fibres of the Trapezius, will retract the scapula.

II. THE MUSCLES CONNECTING THE UPPER EXTREMITY TO THE ANTERIOR AND LATERAL THORACIC WALLS.

The muscles of the anterior and lateral thoracic regions are:

Pectoralis major.

Subclavius.

Pectoralis minor.

Serratus anterior.

Dissection of Pectoral Region and Axilla (Fig. 518).—The arm being drawn away from the side nearly at right angles with the trunk and rotated outward, make a vertical incision through the integument in the median line of the thorax, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoralis major muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downward, along the interspace between the Pectoralis major and Deltoideus muscles, as low as the fold of the axilla. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed,

as it should be replaced on completing the dissection. If a transverse incision is now made from the lower end of the sternum to the side of the thorax, as far as the posterior fold of the axilla, and the integument reflected outward, the axillary space will be more completely exposed.

Superficial Fascia.—The superficial fascia of the anterior thoracic region is continuous with that of the neck and upper extremity above, and of the abdomen

FIG. 518.—Dissection of the upper extremity.

below. It encloses the mamma and gives off numerous septa which pass into the gland, supporting its various lobes. From the fascia over the front of the mamma, fibrous processes pass forward to the integument and papilla; these were called by Sir A. Cooper the *ligamenta suspensoria*.

Pectoral Fascia.—The pectoral fascia is a thin lamina, covering the surface of the Pectoralis major, and sending numerous prolongations between its fasciculi: it is attached, in the middle line, to the front of the sternum; above, to the clavicle; laterally and below it is continuous with the fascia of the shoulder, axilla, and thorax. It is very thin over the upper part of the Pectoralis major, but thicker in the interval between it and the Latissimus dorsi, where it closes in the axillary space and forms the *axillary fascia*; it divides at the lateral margin of the Latissimus dorsi into two layers, one of which passes in front of, and the other behind it; these proceed as far as the spinous processes of the thoracic vertebræ, to which they are

attached. As the fascia leaves the lower edge of the Pectoralis major to cross the floor of the axilla it sends a layer upward under cover of the muscle; this lamina splits to envelop the Pectoralis minor, at the upper edge of which it is continuous with the coracoclavicular fascia. The hollow of the armpit, seen when the arm is abducted, is produced mainly by the traction of this fascia on the axillary floor, and hence the lamina is sometimes named the *suspensory ligament of the axilla*. At the lower part of the thoracic region the deep fascia is well-developed, and is continuous with the fibrous sheaths of the Recti abdominis.

Applied Anatomy.—In cases of suppuration in the axilla, the axillary fascia prevents the extension of the pus in a downward direction, and so it has a tendency to spread upward, beneath the Pectoral muscles, toward the root of the neck. Early evacuation is therefore necessary. The incision should be made midway between the anterior and posterior axillary folds, so as to avoid the lateral thoracic and subscapular vessels, and the edge of the knife should be directed away from the axillary vessels.

The **Pectoralis major** (Fig. 519) is a thick, triangular muscle, situated at the upper and forepart of the chest. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; from the cartilages of all the true ribs, with the exception, frequently, of the first or seventh, or both, and from the aponeurosis of the Obliquus externus abdominis. From this

extensive origin the fibres converge toward their insertion; those arising from the clavicle pass obliquely downward and lateralward, and are usually separated from the rest by a slight interval; those from the lower part of the sternum, and the cartilages of the lower true ribs, run upward and lateralward; while the middle fibres pass horizontally. They all end in a flat tendon, about 5 cm. broad, which is inserted into the crest of the greater tubercle of the humerus. This tendon consists of two laminae, placed one in front of the other, and usually blended together below. The anterior lamina, the thicker, receives the clavicular and the uppermost

FIG. 519.—Superficial muscles of the chest and front of the arm.

sternal fibres; they are inserted in the same order as that in which they arise: that is to say, the most lateral of the clavicular fibres are inserted at the upper part of the anterior lamina; the uppermost sternal fibres pass down to the lower part of the lamina which extends as low as the tendon of the Deltoides and joins with it. The posterior lamina of the tendon receives the attachment of the greater part of the sternal portion and the deep fibres, *i. e.*, those from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend the higher, turning backward successively behind the superficial and upper ones,

so that the tendon appears to be twisted. The posterior lamina reaches higher on the humerus than the anterior one, and from it an expansion is given off which covers the intertubercular groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the intertubercular groove, while from the lower border of the tendon a third expansion passes downward to the fascia of the arm.

Relations.—The Pectoralis major is in relation by its *anterior surface* with the integument, the superficial fascia, the Platysma, the anterior and middle supraclavicular nerves, the mamma, and the deep fascia; by its *posterior surface*, with the sternum, the ribs and costal cartilages, the coracoclavicular fascia, the Subclavius, Pectoralis minor, Serratus anterior, and the Intercostales; it forms the anterior wall of the axillary space, and covers the axillary vessels and nerves and the Biceps brachii and Coracobrachialis. Its *upper border* lies parallel with the Deltoideus, from which it is separated by a slight interspace in which lie the cephalic vein and deltoid branch of the thoracoacromial artery. Its *lower border* forms the anterior fold of the axilla, being separated medially from the Latissimus dorsi by a considerable interval; but the two muscles gradually converge toward the lateral part of the space.

Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to its line of attachment to the sternum and costal cartilages. The muscle should then be reflected outward, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the coracoclavicular fascia.

Coracoclavicular Fascia (*fascia coracoclavicularis*; *costocoracoid membrane*; *clavipectoral fascia*).—The coracoclavicular fascia is a strong fascia situated under cover of the clavicular portion of the Pectoralis major. It occupies the interval between the Pectoralis minor and Subclavius, and protects the axillary vessels and nerves. Traced upward, it splits to enclose the Subclavius, and its two layers are attached to the clavicle, one in front of and the other behind the muscle; the latter layer fuses with the deep cervical fascia and with the sheath of the axillary vessels. Medially, it blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib medial to the origin of the Subclavius. Laterally, it is very thick and dense, and is attached to the coracoid process. The portion extending from the first rib to the coracoid process is often whiter and denser than the rest, and is sometimes called the *costocoracoid ligament*. Below this it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle; from the lower border of the Pectoralis minor it is continued downward to join the axillary fascia, and lateralward to join the fascia over the short head of the Biceps brachii. The coracoclavicular fascia is pierced by the cephalic vein, thoracoacromial artery and vein, and external anterior thoracic nerve.

The **Pectoralis minor** (Fig. 520) is a thin, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It *arises* from the upper margins and outer surfaces of the third, fourth, and fifth ribs, near their cartilage and from the aponeuroses covering the Intercostalis; the fibres pass upward and lateralward and converge to form a flat tendon, which is inserted into the medial border and upper surface of the coracoid process of the scapula.

Relations.—By its *anterior surface* it is in relation with the Pectoralis major, the lateral anterior thoracic nerve, and the pectoral branch of the thoracoacromial artery; by its *posterior surface*, with the ribs, Intercostales, Serratus anterior, the axillary space, and the axillary vessels and brachial plexus of nerves. Its *upper border* is separated from the clavicle by a narrow triangular interval occupied by the coracoclavicular fascia, behind which are the axillary vessels and nerves. Running parallel to the *lower border* of the muscle is the lateral thoracic artery, and piercing the muscle is the medial anterior thoracic nerve.

The **Subclavius** (Fig. 520) is a small triangular muscle, placed between the clavicle and the first rib. It *arises* by a short, thick tendon from the first rib and its cartilage at their junction, in front of the costoclavicular ligament; the fleshy

fibres proceed obliquely upward and lateralward, to be *inserted* into the groove on the under surface of the clavicle between the costoclavicular and conoid ligaments.

Relations.—Its *deep surface* is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the coraco-clavicular fascia, which, with the clavicle, forms an osseofibrous sheath for the muscle.

The **Serratus anterior** (*Serratus magnus*) (Fig. 520) is a thin muscular sheet, situated between the ribs and the scapula at the upper and lateral part of the chest. It *arises* by fleshy digitations from the outer surfaces and superior borders of the upper eight or nine ribs, and from the aponeuroses covering the intervening Intercostales. Each digitation (except the first) arises from the

radius

FIG. 520.—Deep muscles of the chest and front of the arm, with the boundaries of the axilla.

corresponding rib; the first springs from the first and second ribs; and from the fascia covering the first intercostal space. From this extensive attachment the fibres pass backward, closely applied to the chest-wall, and reach the vertebral border of the scapula, and are inserted into its ventral surface in the following manner. The first digitation is inserted into a triangular area on the ventral surface of the medial angle. The next two digitations spread out to form a thin, triangular sheet, the base of which is directed backward and is inserted into nearly the whole length of the ventral surface of the vertebral border. The lower five or six digitations converge to form a fan-shaped mass, the apex of which is inserted, by muscular and tendinous fibres, into a triangular impression on the ventral surface of the inferior angle. The lower four slips interdigitate at their origins with the upper five slips of the Obliquus externus abdominis.

Relations.—This muscle is partly covered, in front, by the Pectorales and by the mamma: behind, by the Subscapularis. The axillary vessels and nerves lie upon its upper part, while its deep surface rests upon the ribs and Intercostales.

Nerves.—The Pectoralis major is supplied by the medial and lateral anterior thoracic nerves; through these nerves the muscle receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the eighth cervical and first thoracic nerves through the medial anterior thoracic nerve. The Subclavius is supplied by a filament from the fifth and sixth cervical nerves; the Serratus anterior is supplied by the long thoracic, which is derived from the fifth, sixth, and seventh cervical nerves.

Actions.—If the arm has been raised by the Deltoideus, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forward the arm, bringing it across the front of the chest, and at the same time rotates it inward. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downward and medialward toward the thorax, and throwing the inferior angle backward. The Subclavius depresses the shoulder, carrying it downward and forward. When the arms are fixed, all three of these muscles act upon the ribs; drawing them upward and expanding the chest, and thus becoming very important agents in forced inspiration. The Serratus anterior, as a whole, carries the scapula forward, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forward the lower angle and assist the Trapezius in rotating the bone at the sternoclavicular joint, and thus assist this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoideus in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus rotates. After the Deltoideus has raised the arm to a right angle with the trunk, the Serratus anterior and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus anterior may assist in raising and everting the ribs; but it is not the important inspiratory muscle it was formerly believed to be.

Applied Anatomy.—When the Serratus anterior is paralyzed, the vertebral border, and especially the lower angle of the scapula, leave the ribs and stand out prominently on the surface, giving a peculiar "winged" appearance to the back (p. 309). The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

III. THE MUSCLES AND FASCIAE OF THE SHOULDER.

In this group are included:

Deltoideus.
Subscapularis.
Supraspinatus.

Infraspinatus.
Teres minor.
Teres major.

Dissection.—After completing the dissection of the axilla, if the muscles of the back have been dissected, the upper extremity should be separated from the trunk. Saw through the clavicle at its centre, and then cut through the muscles which connect the scapula and arm with the trunk—viz., the Pectoralis minor in front, Serratus anterior at the side, and the Levator anguli, the Rhomboideus, Trapezius, and Latissimus dorsi behind. These muscles should be cleaned and traced to their respective insertions. Then make an incision through the integument, commencing at the outer third of the clavicle, and extending along the margin of that bone, the acromion process, and spine of the scapula; the integument should be dissected from above downward and outward, when the fascia covering the Deltoideus will be exposed (Fig. 518, No. 3).

Deep Fascia.—The deep fascia covering the Deltoideus invests the muscle, and sends numerous septa between its fasciculi. In front it is continuous with the fascia covering the Pectoralis major; behind, where it is thick and strong, with that covering the Infraspinatus; above, it is attached to the clavicle, the acromion, and the spine of the scapula; below, it is continuous with the deep fascia of the arm.

The **Deltoideus** (*Deltoid muscle*) (Fig. 519) is a large, thick, triangular muscle, which covers the shoulder-joint in front, behind, and laterally. It *arises* from the anterior border and upper surface of the lateral third of the clavicle; from the lateral margin

and upper surface of the acromion, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its medial end. From this extensive origin the fibres converge toward their insertion, the middle passing vertically, the anterior obliquely backward and lateralward, the posterior obliquely forward and lateralward; they unite in a thick tendon, which is inserted into the deltoid prominence on the middle of the lateral side of the body of the humerus. At its *insertion* the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion—consists of oblique fibres; these arise in a bipenniform manner from the sides of the tendinous intersections, generally four in number, which are attached above to the acromion and pass downward parallel to one another in the substance of the muscle. The oblique fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upward from the insertion of the muscle and alternate with the descending septa. The portions of the muscle arising from the clavicle and spine of the scapula are not arranged in this manner, but are inserted into the margins of the inferior tendon.

Relations.—The Deltoides is in relation by its *superficial surface* with the integument, the superficial and deep fasciæ, Platysma, and posterior supraclavicular nerves. Its *deep surface* is separated from the capsule of the shoulder-joint by a large bursa, and covers the coracoid process, coracoacromial ligament, Pectoralis minor, Coracobrachialis, both heads of the Biceps brachii, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the long and lateral heads of the Triceps brachii, the humeral circumflex vessels, the axillary nerve, and the upper part of the body of the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by a narrow interval, which lodges the cephalic vein and deltoid branch of the thoracoacromial artery; lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps.

Nerves.—The Deltoides is supplied by the fifth and sixth cervical through the axillary nerve.

Actions.—The Deltoides raises the arm from the side, so as to bring it at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forward; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backward.

Applied Anatomy.—The Deltoides is very liable to atrophy, and in this condition dislocation of the shoulder-joints is simulated, as there is flattening of the shoulder and apparent prominence of the acromion; the distance also between the acromion and the head of the bone is increased, and the tips of the fingers can be inserted between them. Atrophy of the Deltoides may be due to disuse, such as follows chronic arthritis or permanent injury of the shoulder-joint. It also frequently results from degenerations occurring in the medulla spinalis, or injury to the axillary nerve ("crutch palsy"). The Deltoides, Supraspinatus, and Infraspinatus often escape in myopathic atrophies affecting the other muscles of the upper arm or shoulder in young persons.

Dissection.—Divide the Deltoides across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process and spine of the scapula, and reflect it downward, when the structures under cover of it will be seen.

Subscapular Fascia (*fascia subscapularis*).—The subscapular fascia is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its deep surface to some of the fibres of the Subscapularis.

The **Subscapularis** (Fig. 520) is a large triangular muscle which fills the subscapular fossa, and *arises* from its medial two-thirds and from the lower two-thirds of the groove on the axillary border of the bone. Some fibres *arise* from tendinous laminae which intersect the muscle and are attached to ridges on the bone; others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps brachii. The fibres pass lateralward, and, gradually converging, end in a tendon which is *inserted* into the lesser tubercle of the humerus and the front of the capsule of the shoulder-joint. The tendon of the muscle is separated from the neck of the scapula by a large bursa, which communicates with the cavity of the shoulder-joint through an aperture in the capsule.

Relations.—The *anterior surface* of this muscle forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus anterior, Coracobrachialis, and Biceps brachii, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is in relation with the scapula and the capsule of the shoulder-joint. Its *lower border* is in contact with the Teres major and Latissimus dorsi.

Nerves.—The Subscapularis is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inward; when the arm is raised, it draws the humerus forward and downward. It is a powerful defence to the front of the shoulder-joint, preventing displacement of the head of the humerus.

Dissection.—To expose these muscles, and to examine their insertion into the humerus, detach the Deltoides and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula; divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

FIG. 521.—Muscles on the dorsum of the scapula, and the Triceps brachii.

Supraspinatous Fascia (*fascia supraspinata*).—The supraspinatous fascia completes the osseofibrous case in which the Supraspinatus muscle is contained; it affords attachment, by its deep surface, to some of the fibres of the muscle. It is thick medially, but thinner laterally under the coracoacromial ligament.

The **Supraspinatus** (Fig. 521) occupies the whole of the supraspinatous fossa, arising from its medial two-thirds, and from the strong supraspinatous fascia. The muscular fibres converge to a tendon, which crosses the upper part of the shoulder-joint, and is inserted into the highest of the three impressions on the greater tubercle of the humerus; the tendon is intimately adherent to the capsule of the shoulder-joint.

Infraspinatus Fascia (*fascia infraspinata*).—The infraspinatus fascia is a dense fibrous membrane, covering the Infraspinatus muscle and fixed to the circumference of the infraspinatus fossa; it affords attachment, by its deep surface, to some fibres of that muscle. It is intimately attached to the deltoid fascia along the overlapping border of the Deltoideus.

The **Infraspinatus** (Fig. 521) is a thick triangular muscle, which occupies the chief part of the infraspinatus fossa; it *arises* by fleshy fibres from its medial two-thirds, and by tendinous fibres from the ridges on its surface; it also arises from the infraspinatus fascia which covers it, and separates it from the Teretes major and minor. The fibres converge to a tendon, which glides over the lateral border of the spine of the scapula, and, passing across the posterior part of the capsule of the shoulder-joint, is *inserted* into the middle impression on the greater tubercle of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a bursa, which may communicate with the joint cavity.

The **Teres minor** (Fig. 521) is a narrow, elongated muscle, which *arises* from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminae, one of which separates it from the *Infraspinatus*, the other from the *Teres major*. Its fibres run obliquely upward and lateralward; the upper ones end in a tendon which is *inserted* into the lowest of the three impressions on the greater tubercle of the humerus; the lowest fibres are *inserted* directly into the humerus immediately below this impression. The tendon of this muscle passes across, and is united with, the posterior part of the capsule of the shoulder-joint.

The **Teres major** (Fig. 521) is a thick but somewhat flattened muscle, which *arises* from the oval area on the dorsal surface of the inferior angle of the scapula, and from the fibrous septa interposed between the muscle and the *Teres minor* and *Infraspinatus*; the fibres are directed upward and lateralward, and end in a flat tendon, about 5 cm. long, which is *inserted* into the crest of the lesser tubercle of the humerus. The tendon, at its insertion, lies behind that of the *Latissimus dorsi*, from which it is separated by a bursa, the two tendons being, however, united along their lower borders for a short distance.

Nerves.—The *Supraspinatus* and *Infraspinatus* are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the *Teres minor*, by the fifth cervical, through the axillary; and the *Teres major*, by the fifth and sixth cervical, through the lowest subscapular.

Actions.—The *Supraspinatus* assists the *Deltoideus* in raising the arm from the side of the trunk and fixes the head of the humerus in the glenoid cavity. The *Infraspinatus* and *Teres minor* rotate the head of the humerus outward; they also assist in carrying the arm backward. One of the most important uses of these three muscles is to protect the shoulder-joint, the *Supraspinatus* supporting it above, and the *Infraspinatus* and *Teres minor* behind. The *Teres major* assists the *Latissimus dorsi* in drawing the previously raised humerus downward and backward, and in rotating it inward; when the arm is fixed it may assist the *Pectorales* and the *Latissimus dorsi* in drawing the trunk forward.

IV. THE MUSCLES AND FASCIÆ OF THE ARM.

The muscles of the arm are:

Coracobrachialis.
Biceps brachii.

Brachialis.
Triceps brachii.

Dissection.—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the clavicle to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (Fig. 518).

Brachial Fascia (*fascia brachii*; *deep fascia of the arm*).—The brachial fascia is continuous with that covering the Deltoides and the Pectoralis major, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula; it forms a thin, loose, membranous sheath for the muscles of the arm, and sends septa between them; it is composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being thin over the Biceps brachii, but thicker where it covers the Triceps brachii, and over the epicondyles of the humerus: it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi medially, and from the Deltoides laterally. On either side it gives off a strong intermuscular septum, which is attached to the corresponding supracondylar ridge and epicondyle of the humerus. The **lateral intermuscular septum** extends from the lower part of the crest of the greater tubercle, along the lateral supracondylar ridge, to the lateral epicondyle; it is blended with the tendon of the Deltoides, gives attachment to the Triceps brachii behind, to the Brachialis, Brachioradialis, and Extensor carpi radialis longus in front, and is perforated by the radial nerve and profunda branch of the brachial artery. The **medial intermuscular septum**, thicker than the preceding, extends from the lower part of the crest of the lesser tubercle of the humerus below the Teres major, along the medial supracondylar ridge to the medial epicondyle; it is blended with the tendon of the Coracobrachialis, and affords attachment to the Triceps brachii behind and the Brachialis in front. It is perforated by the ulnar nerve, the superior ulnar collateral artery, and the posterior branch of the inferior ulnar collateral artery. At the elbow, the deep fascia is attached to the epicondyles of the humerus and the olecranon of the ulna, and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its medial side, is an oval opening in the deep fascia, which transmits the basilic vein and some lymphatic vessels.

The **Coracobrachialis** (Fig. 520), the smallest of the three muscles in this region, is situated at the upper and medial part of the arm. It *arises* from the apex of the coracoid process, in common with the short head of the Biceps brachii, and from the intermuscular septum between the two muscles; it is *inserted* by means of a flat tendon into an impression at the middle of the medial surface and border of the body of the humerus between the origins of the Triceps brachii and Brachialis. It is perforated by the musculocutaneous nerve.

Relations.—The Coracobrachialis is in relation, in *front*, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it; *behind*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the medial head of the Triceps brachii, the humerus, and the anterior humeral circumflex vessels; by its *medial border*, with the third part of the axillary and upper part of the brachial artery and the median and musculocutaneous nerves; by its *lateral border*, with the short head of the Biceps brachii and Brachialis.

The **Biceps brachii** (*Biceps*; *Biceps flexor cubiti*) (Fig. 520) is a long fusiform muscle, placed on the front of the arm, and *arising* by two heads, from which circumstance it has received its name. The **short head** *arises* by a thick flattened tendon from the apex of the coracoid process, in common with the Coracobrachialis. The **long head** *arises* from the supraglenoid tuberosity at the upper margin of the glenoid cavity, and is continuous with the glenoidal labrum. This tendon, enclosed in a special sheath of the synovial membrane of the shoulder-joint, arches over the head of the humerus; it emerges from the capsule through an opening close to the humeral attachment of the ligament, and descends in the intertubercular groove; it is retained in the groove by the transverse humeral ligament and by a fibrous prolongation from the tendon of the Pectoralis major. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can readily be separated until within about 7.5 cm. of the elbow-joint. Here they end in a flattened tendon, which is inserted into the rough

posterior portion of the tuberosity of the radius, a bursa being interposed between the tendon and the front part of the tuberosity. As the tendon of the muscle approaches the radius it is twisted upon itself, so that its anterior surface becomes lateral and is applied to the tuberosity of the radius at its insertion. Opposite the bend of the elbow the tendon gives off, from its medial side, a broad aponeurosis, the **lacertus fibrosus** (*bicipital fascia*) which passes obliquely downward and medialward across the brachial artery, and is continuous with the deep fascia covering the origins of the Flexor muscles of the forearm (Fig. 519).

A third head to the Biceps brachii is occasionally found, arising at the upper and medial part of the Brachialis, with the fibres of which it is continuous, and inserted into the lacertus fibrosus and medial side of the tendon of the muscle. In most cases this additional slip lies behind the brachial artery in its course down the arm. In some instances the third head consists of two slips, which pass down, one in front of and the other behind the artery, concealing the vessel in the lower half of the arm.

Relations.—The Biceps brachii is overlapped above by the Pectoralis major and Deltoideus; in the rest of its extent it is covered by the superficial and deep fasciæ and the integument. It rests above on the shoulder-joint and upper part of the humerus; below, it lies on the Brachialis, the musculocutaneous nerve, and the Supinator. Its *medial border* is in relation with the Coracobrachialis, and overlaps the brachial vessels and median nerve; its *lateral border*, with the Deltoideus and Brachioradialis.

The **Brachialis** (*Brachialis anticus*) (Fig. 520) covers the front of the elbow-joint and the lower half of the humerus. It *arises* from the lower half of the front of the humerus, commencing above at the insertion of the Deltoideus, which it embraces by two angular processes. Its origin extends below to within 2.5 cm. of the margin of the articular surface. It also arises from the intermuscular septa, but more extensively from the medial than the lateral; it is separated from the lateral below by the Brachioradialis and Extensor carpi radialis longus. Its fibres converge to a thick tendon, which is *inserted* into the tuberosity of the ulna and the rough depression on the anterior surface of the coronoid process.

Relations.—The Brachialis is in relation, in *front*, with the Biceps brachii, the brachial vessels, musculocutaneous and median nerves; *behind*, with the humerus and front of the elbow-joint; by its *medial border*, with the Triceps brachii, ulnar nerve, and Pronator teres, from which it is separated by the intermuscular septum; by its *lateral border*, with the radial nerve, radial recurrent artery, the Brachioradialis and Extensor carpi radialis longus.

Nerves.—The Coracobrachialis, Biceps brachii and Brachialis are supplied by the musculocutaneous nerve; the Brachialis usually receives an additional filament from the radial. The Coracobrachialis receives its supply primarily from the seventh cervical, the Biceps brachii and Brachialis from the fifth and sixth cervical nerves.

Actions.—The Coracobrachialis draws the humerus forward and medialward, and at the same time assists in retaining the head of the bone in contact with the glenoid cavity. The Biceps brachii is a flexor of the elbow and, to a less extent, of the shoulder; it is also a powerful supinator, and serves to render tense the deep fascia of the forearm by means of the lacertus fibrosus given off from its tendon. The Brachialis is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps brachii and Brachialis flex the arm upon the forearm, as in efforts of climbing.

Applied Anatomy.—The long tendon of the Biceps brachii is sometimes dislocated from the intertubercular groove. When this has taken place, the arm is fixed in a position of abduction, but the head of the humerus can be felt in its proper position. It can generally be replaced by flexing the forearm on the arm and rotating the limb. Rupture of the long tendon of the Biceps brachii may also take place.

The **Triceps brachii** (*Triceps*; *Triceps extensor cubiti*) (Fig. 521) is situated on the back of the arm, extending the entire length of the dorsal surface of the humerus. It is of large size, and arises by three heads (long, lateral, and medial), hence its name.

The **long head** *arises* by a flattened tendon from the infraglenoid tuberosity of the scapula, being blended at its upper part with the capsule of the shoulder-joint; the muscular fibres pass downward between the two other heads of the muscle, and join with them in the tendon of insertion.

The **lateral head** *arises* from the posterior surface of the body of the humerus, between the insertion of the Teres minor and the upper part of the groove for the radial nerve, and from the lateral border of the humerus and the lateral intermuscular septum; the fibres from this origin converge toward the tendon of insertion.

The **medial head** *arises* from the posterior surface of the body of the humerus, below the groove for the radial nerve; it is narrow and pointed above, and extends from the insertion of the Teres major to within 2.5 cm. of the trochlea: it also arises from the medial border of the humerus and from the back of the whole length of the medial intermuscular septum. Some of the fibres are directed downward to the olecranon, while others converge to the tendon of insertion.

The **tendon of the Triceps brachii** begins about the middle of the muscle: it consists of two aponeurotic laminae, one of which is subcutaneous and covers the back of the lower half of the muscle; the other is more deeply seated in the substance of the muscle. After receiving the attachment of the muscular fibres, the two lamellae join together above the elbow, and are inserted, for the most part, into the posterior portion of the upper surface of the olecranon; a band of fibres is, however, continued downward, on the lateral side, over the Anconaeus, to blend with the deep fascia of the forearm.

The long head of the Triceps brachii descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (Fig. 521). The triangular space contains the scapular circumflex vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps laterally. The quadrangular space transmits the posterior humeral circumflex vessels and the axillary nerve; it is bounded by the Teres minor and capsule of the shoulder-joint above, the Teres major below, the long head of the Triceps brachii medially, and the humerus laterally.

The **Subanconaeus** is the name given to a few fibres which spring from the deep surface of the lower part of the Triceps brachii, and are inserted into the posterior ligament and synovial membrane of the elbow-joint.

Nerves.—The Triceps brachii is supplied by the seventh and eighth cervical nerves through the radial nerve.

Actions.—The Triceps brachii is the great extensor muscle of the forearm, and is the direct antagonist of the Biceps brachii and Brachialis. When the arm is extended, the long head of the muscle may assist the Teres major and Latissimus dorsi in drawing the humerus backward and in adducting it to the thorax. The long head supports the under part of the shoulder-joint. The Subanconaeus draws up the synovial membrane of the elbow-joint during extension of the forearm.

Applied Anatomy.—The continuity of the insertion of the Triceps brachii with the deep fascia of the forearm is of importance in the operation of excision of the elbow; it should always be carefully preserved from injury. By means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise be accomplished mainly by gravity—that is to say, by allowing the forearm to drop by its own weight.

V. THE MUSCLES AND FASCIA OF THE FOREARM.

Dissection.—To dissect the forearm, place the limb in the position indicated in Fig. 518, make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

Antibrachial Fascia (*fascia antibrachii; deep fascia of the forearm*).—The antibrachial fascia continuous above with the brachial fascia, is a dense, membranous investment, which forms a general sheath for the muscles in this region; it is attached, *behind*, to the olecranon and dorsal border of the ulna, and gives off from its deep surface numerous intermuscular septa, which enclose each muscle separately. Over the Flexor tendons as they approach the wrist it is especially thickened, and forms the volar carpal ligament. This is continuous with the transverse carpal ligament, and forms a sheath for the tendon of the Palmaris longus which passes over the transverse carpal ligament to be inserted into the palmar aponeurosis. *Behind*,

near the wrist-joint, it is thickened by the addition of many transverse fibres, and forms the dorsal carpal ligament. It is much thicker on the dorsal than on the volar surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Biceps brachii in front, and from the Triceps brachii behind. It gives origin to muscular fibres, especially at the upper part of the medial and lateral sides of the forearm, and forms the boundaries of a series of cone-shaped cavities, in which the muscles are contained. Besides the vertical septa separating the individual muscles, transverse septa are given off both on the volar and dorsal surfaces of the forearm, separating the deep from the superficial layers of muscles. Apertures exist in the fascia for the passage of vessels and nerves; one of these apertures of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins.

The antibrachial or forearm muscles may be divided into a **volar** and a **dorsal** group.

1. The Volar Antibrachial Muscles.

These muscles are divided for convenience of description into two groups, superficial and deep.

The Superficial Group (Fig. 522).

Pronator teres.

Palmaris longus.

Flexor carpi radialis.

Flexor carpi ulnaris.

Flexor digitorum sublimis.

The muscles of this group take origin from the medial epicondyle of the humerus by a common tendon; they receive additional fibres from the deep fascia of the forearm near the elbow, and from the septa which pass from this fascia between the individual muscles.

The **Pronator teres** has two heads of origin—humeral and ulnar. The **humeral head**, the larger and more superficial, *arises* immediately above the medial epicondyle, and from the tendon common to the origin of the other muscles; also from the intermuscular septum between it and the Flexor carpi radialis and from the antibrachial fascia. The **ulnar head** is a thin fasciculus, which *arises* from the medial side of the coronoid process of the ulna, and joins the preceding at an acute angle. The median nerve enters the forearm between the two heads of the muscle, and is separated from the ulnar artery by the ulnar head. The muscle passes obliquely across the forearm, and ends in a flat tendon, which is inserted into a rough impression at the middle of the lateral surface of the body of the radius. The lateral border of the muscle forms the medial boundary of a triangular hollow situated in front of the elbow-joint and containing the brachial artery, median nerve, and tendon of the Biceps brachii.

Applied Anatomy.—This muscle, when suddenly brought into active use, as in the game of lawn tennis, is apt to be strained, producing slight swelling, tenderness, and pain on putting the muscle, into action. This is known as "lawn-tennis arm."

The **Flexor carpi radialis** lies on the medial side of the preceding muscle. It *arises* from the medial epicondyle by the common tendon; from the fascia of the forearm; and from the intermuscular septa between it and the Pronator teres laterally, the Palmaris longus medially, and the Flexor digitorum sublimis beneath. Slender and aponeurotic in structure at its commencement, it increases in size, and ends in a tendon which forms rather more than the lower half of its length. This tendon passes through a canal in the lateral part of the transverse carpal ligament and runs through a groove on the greater multangular bone; the groove is converted into a canal by fibrous tissue, and lined by a mucous sheath. The tendon is inserted into the base of the second metacarpal bone, and sends a slip to

the base of the third metacarpal bone. The radial artery, in the lower part of the forearm, lies between the tendon of this muscle and the Brachioradialis.

The **Palmaris longus** is a slender, fusiform muscle, lying on the medial side of the preceding. It *arises* from the medial epicondyle of the humerus by the common tendon, from the intermuscular septa between it and the adjacent muscles, and from the anti-brachial fascia. It ends in a slender,

FIG. 522.—Front of the left forearm. Superficial muscles.

FIG. 523.—Front of the left forearm. Deep muscles.

flattened tendon, which passes over the upper part of the transverse carpal ligament, and is *inserted* into the central part of the transverse carpal ligament and lower part of the palmar aponeurosis, frequently sending a tendinous slip to the short muscles of the thumb.

This muscle is often absent, and is subject to very considerable variations; it may be tendinous above and muscular below; or it may be muscular in the centre with a tendon above and below; or it may present two muscular bundles with a central tendon; or finally it may consist solely of a tendinous band. Just above the wrist, the median nerve lies close to the tendon, on its lateral and dorsal aspects.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It *arises* by two heads, humeral and ulnar, connected by a tendinous arch, beneath which the ulnar nerve and posterior ulnar recurrent artery pass. The **humeral head** *arises* from the medial epicondyle of the humerus by the common tendon; the **ulnar head** *arises* from the medial margin of the olecranon and from the upper two-thirds of the dorsal border of the ulna by an aponeurosis, common to it and the Extensor carpi ulnaris and Flexor digitorum profundus; and from the intermuscular septum between it and the Flexor digitorum sublimis. The fibres end in a tendon, which occupies the anterior part of the lower half of the muscle and is *inserted* into the pisiform bone, and is prolonged from this to the hamate and fifth metacarpal bones by the pisohamate and pisometacarpal ligaments; it is also attached by a few fibres to the transverse carpal ligament. The ulnar vessels and nerve lie on the lateral side of the tendon of this muscle, in the lower two-thirds of the forearm.

The **Flexor digitorum sublimis** is placed beneath the previous muscle; it is the largest of the muscles of the superficial group, and arises by three heads—humeral, ulnar, and radial. The **humeral head** *arises* from the medial epicondyle of the humerus by the common tendon, from the ulnar collateral ligament of the elbow-joint, and from the intermuscular septa between it and the preceding muscles. The **ulnar head** *arises* from the medial side of the coronoid process, above the ulnar origin of the Pronator teres (see Fig. 353, page 316). The **radial head** *arises* from the oblique line of the radius, extending from the radial tuberosity to the insertion of the Pronator teres. The muscle speedily separates into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane gives off a muscular slip to join the portion of the superficial plane which is associated with the tendon of the ring finger, and then divides into two parts, which end in tendons for the index and little fingers. As the four tendons thus formed pass beneath the transverse carpal ligament into the palm of the hand, they are arranged in pairs, the superficial pair going to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another in the palm and form dorsal relations to the superficial volar arch and digital branches of the median and ulnar nerves. Opposite the bases of the first phalanges each tendon divides into two slips to allow of the passage of the corresponding tendon of the Flexor digitorum profundus; the two slips then reunite and form a grooved channel for the reception of the accompanying tendon of the Flexor digitorum profundus. Finally the tendon divides and is inserted into the sides of the second phalanx about its middle.

The Deep Group (Fig. 523).

Flexor digitorum profundus.

Flexor pollicis longus.

Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed

The **Flexor digitorum profundus** is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It *arises* from the upper three-fourths of the volar and medial surfaces of the body of the ulna, embracing the insertion of the Brachialis above, and extending below to within a short distance of the Pronator quadratus. It also arises from a depression on the medial side of the coronoid process; by an aponeurosis from the upper three-fourths of the dorsal border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The muscle ends in four tendons which run under the transverse carpal ligament dorsal to the tendons of the Flexor digitorum sublimis. Opposite the first phalanges the tendons pass through the openings in the tendons of the Flexor digitorum sublimis, and are finally *inserted* into the bases of the last phalanges. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the middle, ring, and little fingers are connected together by areolar tissue and tendinous slips, as far as the palm of the hand.

Fibrous Sheaths of the Flexor Tendons.—After leaving the palm, the tendons of the Flexores digitorum sublimis and profundus lie in osseo-aponeurotic canals (Fig. 534), formed behind by the phalanges and in front by strong fibrous bands, which arch across the tendons, and are attached on either side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the bands (digital vaginal ligaments) are very strong, and the fibres are transverse; but opposite the joints they are much thinner, and consist of *annular* and *cruciate* ligamentous fibres. Each canal contains a mucous sheath, which is reflected on the contained tendons.

Within each canal the tendons of the Flexores digitorum sublimis and profundus are connected to each other, and to the phalanges, by slender, tendinous bands, called **vincula tendina** (Fig. 524). There are two sets of these; (a) the **vincula brevia**, which are two in number in each finger, and consist of triangular bands of fibres, one connecting the tendon of the Flexor digitorum sublimis to the front of the first interphalangeal joint and head of the first phalanx, and the other the tendon of the Flexor digitorum profundus to the front of the second interphalangeal joint and head of the second phalanx; (b) the **vincula longa**, which connect the under surfaces of the tendons of the Flexor digitorum profundus to those of the subjacent Flexor sublimis after the tendons of the former have passed through the latter.

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles of the hand (page 555).

The **Flexor pollicis longus** is situated on the radial side of the forearm, lying in the same plane as the preceding. It *arises* from the grooved volar surface of the body of the radius, extending from immediately below the tuberosity and oblique line to within a short distance of the Pronator quadratus. It *arises* also from the adjacent part of the interosseous membrane, and generally by a fleshy slip from the medial border of the coronoid process, or from the medial epicondyle of the humerus. The fibres end in a flattened tendon, which passes beneath the transverse carpal ligament, is then lodged between the lateral head of the Flexor pollicis brevis and the oblique part of the Adductor pollicis, and, entering an osseo-aponeurotic canal similar to those for the Flexor tendons of the fingers, is *inserted* into the base of the distal phalanx of the thumb. The volar interosseous nerve and vessels pass downward on the front of the interosseous membrane between the Flexor pollicis longus and Flexor digitorum profundus.

The **Pronator quadratus** is a small, flat, quadrilateral muscle, extending across the front of the lower parts of the radius and ulna. It *arises* from the pronator ridge on the lower part of the volar surface of the body of the ulna; from the medial

part of the volar surface of the lower fourth of the ulna; and from a strong aponeurosis which covers the medial third of the muscle. The fibres pass lateralward and slightly downward, to be inserted into the lower fourth of the lateral border and the volar surface of the body of the radius. The deeper fibres of the muscle are inserted into the triangular area above the ulnar notch of the radius—an attachment comparable with the origin of the Supinator from the triangular area below the radial notch of the ulna.

FIG. 524.—Tendons of forefinger and vincula tendina

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. The Pronator teres, the Flexor carpi radialis, and the Palmaris longus derive their supply primarily from the sixth cervical nerve; the Flexor digitorum sublimis from the seventh and eighth cervical and first thoracic nerves, and the Flexor carpi ulnaris from the eighth cervical and first thoracic. Of the deep layer, the Flexor digitorum profundus is supplied by the eighth cervical and first thoracic through the ulnar, and the volar interosseous branch of the median. The Flexor pollicis longus and Pronator quadratus are supplied by the eighth cervical and first thoracic through the volar interosseous branch of the median.

Actions.—These muscles act upon the forearm, the wrist, and hand. The Pronator teres rotates the radius upon the ulna, rendering the hand prone; when the radius is fixed, it assists in flexing the forearm. The Flexor carpi radialis is a flexor and abductor of the wrist; it also assists in pronating the hand, and in bending the elbow. The Flexor carpi ulnaris is a flexor and adductor of the wrist; it also assists in bending the elbow. The Palmaris longus is a flexor of the wrist-joint; it also assists in flexing the elbow. The Flexor digitorum sublimis flexes first the middle and then the proximal phalanges; it also assists in flexing the wrist and elbow. The Flexor digitorum profundus is one of the flexors of the phalanges. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one; but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The

Flexor pollicis longus is a flexor of the phalanges of the thumb; when the thumb is fixed, it assists in flexing the wrist. The *Pronator quadratus* rotates the radius upon the ulna, rendering the hand prone.

2. The Dorsal Antibrachial Muscles.

These muscles are divided for convenience of description into two groups, superficial and deep.

The Superficial Group (Fig. 525).

<i>Brachioradialis.</i>	<i>Extensor digitorum communis.</i>
<i>Extensor carpi radialis longus.</i>	<i>Extensor digiti quinti proprius.</i>
<i>Extensor carpi radialis brevis.</i>	<i>Extensor carpi ulnaris.</i>
<i>Anconaeus.</i>	

Dissection.—Divide the integument in the same manner as in the dissection of the volar anti-brachial region, and, after having examined the cutaneous vessels and nerves and deep fascia, remove all those structures. The muscles will then be exposed. The removal of the fascia will be considerably facilitated by detaching it from below upward. Great care should be taken to avoid cutting across the tendons of the muscles of the thumb, which cross obliquely the larger tendons running down the back of the radius.

The ***Brachioradialis*** (*Supinator longus*) is the most superficial muscle on the radial side of the forearm. It *arises* from the upper two-thirds of the lateral supracondylar ridge of the humerus, and from the lateral intermuscular septum, being limited above by the groove for the radial nerve. Interposed between it and the *Brachialis* are the radial nerve and the anastomosis between the anterior branch of the profunda artery and the radial recurrent. The fibres end above the middle of the forearm in a flat tendon, which is *inserted* into the lateral side of the base of the styloid process of the radius. The tendon is crossed near its insertion by the tendons of the *Abductor pollicis longus* and *Extensor pollicis brevis*; on its ulnar side is the radial artery.

The ***Extensor carpi radialis longus*** (*Extensor carpi radialis longior*) is placed partly beneath the *Brachioradialis*. It *arises* from the lower third of the lateral supracondylar ridge of the humerus, from the lateral intermuscular septum, and by a few fibres from the common tendon of origin of the *Extensor* muscles of the forearm. The fibres end at the upper third of the forearm in a flat tendon, which runs along the lateral border of the radius, beneath the *Abductor pollicis longus* and *Extensor pollicis brevis*; it then passes beneath the dorsal carpal ligament, where it lies in a groove on the back of the radius common to it and the *Extensor carpi radialis brevis*, immediately behind the styloid process. It is *inserted* into the dorsal surface of the base of the second metacarpal bone, on its radial side.

The ***Extensor carpi radialis brevis*** (*Extensor carpi radialis brevior*) is shorter and thicker than the preceding muscle, beneath which it is placed. It *arises* from the lateral epicondyle of the humerus, by a tendon common to it and the three following muscles; from the radial collateral ligament of the elbow-joint; from a strong aponeurosis which covers its surface; and from the intermuscular septa between it and the adjacent muscles. The fibres end about the middle of the forearm in a flat tendon, which is closely connected with that of the preceding muscle, and accompanies it to the wrist; it passes beneath the *Abductor pollicis longus* and *Extensor pollicis brevis*, then beneath the dorsal carpal ligament, and is *inserted* into the dorsal surface of the base of the third metacarpal bone on its radial side. Under the dorsal carpal ligament the tendon lies on the back of the radius in a shallow groove, to the ulnar side of that which lodges the tendon of the *Extensor carpi radialis, longus*, and separated from it by a faint ridge.

The tendons of the two preceding muscles pass through the same compartment of the dorsal carpal ligament in a single mucous sheath.

MYOLOGY

Extensor digitorum communis arises from the lateral epicondyle of the humerus; from the intermuscular septa between it and the Extensor carpi ulnaris; and from the antibrachial fascia. It divides below into four tendons, together with that of the Extensor indicis proprius, through the substance of the dorsal carpal ligament, within a mucous sheath. They converge on the back of the hand, and are inserted into the second phalanx of the fingers in the following manner. Opposite the metacarpophalangeal articulation each tendon is bound by fasciculi to the collateral ligament of the joint; as the dorsal ligament of this joint; after having crossed the joint, it is continued into a broad aponeurosis, which covers the dorsal surface of the hand and is reinforced, in this situation, by the tendons of the Interossei. Opposite the first interphalangeal joint this aponeurosis divides into three parts; an intermediate and two collateral: the former is inserted into the proximal phalanx; and the two collateral, which are continued into the second phalanx, unite by their contiguous margins, to form the dorsal surface of the last phalanx. As the tendons cross the joints, they furnish them with dorsal ligaments. The tendon of the Extensor digitorum communis is accompanied by the Extensor indicis proprius, which lies on the back of the hand, the tendons to the middle, ring, and little fingers are connected by two obliquely placed bands, one from the third to the middle finger and lateralward to the second tendon, and the other from the middle finger downward and medialward to the fourth. Occasion is connected to the second by a thin transverse band.

Extensor digiti quinti proprius (*Extensor minimi digiti*) is a slender muscle on the ulnar side of the Extensor digitorum communis, with which it is connected. It arises from the common Extensor tendon by a thin band, and from the intermuscular septa between it and the adjacent muscles. It passes through a compartment of the dorsal carpal ligament behind the Extensor digitorum communis tendon, then divides into two as it crosses the hand, and finally is inserted into the side of the little finger.

Extensor carpi ulnaris lies on the ulnar side of the forearm. It arises from the lateral epicondyle of the humerus, by the common tendon; by an aponeurotic band from the ulnar border of the ulna in common with the Flexor carpi ulnaris; and from the deep fascia of the forearm. It runs in a groove between the head and the styloid process of the ulna, passing through a separate compartment of the dorsal carpal ligament, and is inserted into the prominent tubercle on the ulnar side of the base of the fifth metacarpal bone.

Extensor carpi radialis longus is a small triangular muscle which is placed on the back of the forearm. It appears to be a continuation of the Triceps brachii. It arises from the back part of the lateral epicondyle of the humerus; and its fibers are inserted into the side of the olecranon, and upper fourth of the body of the ulna.

The Deep Group (Fig. 526).

Extensor pollicis brevis.
Extensor pollicis longus.
Extensor indicis proprius.

Supinator brevis (Fig. 527) is a broad muscle, curved around the radius. It consists of two planes of fibres, between which the radial nerve lies. The two planes arise in common—the superficial by aponeurotic fibres—from the lateral epicondyle of the humerus and the deeper by muscular fibres—from the lateral

epicondyle of the humerus; from the radial collateral ligament of the elbow-joint, and the annular ligament; from the ridge on the ulna, which runs obliquely downward from the dorsal end of the radial notch; from the triangular depression below the notch; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are inserted into the lateral edge of the radial tuberosity and the oblique line of the radius, as low down as the insertion of the Pronator teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its medial surface; the greater part of this portion of the muscle is inserted into the dorsal and lateral surfaces of the body of the radius, midway between the oblique line and the head of the bone.

The **Abductor pollicis longus** (*Extensor oss. metacarpi pollicis*) lies immediately below the Supinator and is sometimes united with it. It arises from the lateral part of the dorsal surface of the body of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the dorsal surface of the body of the radius. Passing obliquely downward and lateralward, it ends in a tendon, which runs through a groove on the lateral side of the lower end of the radius, accompanied by the tendon of the Extensor pollicis brevis, and is inserted into the radial side of the base of the first metacarpal bone. It occasionally gives off two slips near its insertion: one to the greater multangular bone and the other to blend with the origin of the Abductor pollicis brevis.

The **Extensor pollicis brevis** (*Extensor primi internodii pollicis*) lies on the medial side of, and is closely connected with, the Abductor pollicis

longus. It arises from the dorsal surface of the body of the radius below that muscle, and from the interosseous membrane. Its direction is similar to that of the Abductor pollicis longus, its tendon passing through the same groove on the lateral side of the lower end of the radius, to be inserted into the base of the first phalanx of the thumb.

The **Extensor pollicis longus** (*Extensor secundi internodii pollicis*) is much larger than the preceding muscle, the origin of which it partly covers. It arises from the lateral part of the middle third of the dorsal surface of the body of the ulna below the origin of the Abductor pollicis longus, and from the interosseous membrane. It ends in a tendon, which passes through a separate compartment in the dorsal carpal ligament, lying in a narrow, oblique groove on the back of the lower end of the radius. It then crosses obliquely the tendons of the Extensores carpi radialis longus and brevis, and is separated from the Extensor brevis pollicis by a

n which the radial artery is found; and is finally inserted into phalanx of the thumb. The radial artery is crossed by the extensor pollicis longus and of the Extensores pollicis longus and

radialis is supplied by the fifth and sixth, the *Extensores carpi radialis* sixth and seventh, and the *Anconeus* by the seventh and eighth cervical nerve; the remaining muscles are innervated through the deep radial nerve supplied by the sixth, and all the other muscles by the seventh cervical. The muscles of the lateral and dorsal aspects of the forearm, which comprise all the *Supinator*, act upon the forearm, wrist, and hand; they are the *Pronator* and *Flexor* muscles. The *Anconeus* assists the *Triceps* in the *Brachioradialis* is a flexor of the elbow-joint, but only acts as such flexion has been initiated by the *Biceps brachii* and *Brachialis*. The *Extensor carpi radialis longus* extends the wrist and abducts the hand. The *Extensor carpi radialis brevis* extends the wrist, and may also act slightly as an abductor of the wrist, but when acting alone inclines the wrist to the ulnar side; by its continued action it extends the elbow-joint. The *Extensor carpi ulnaris* extends the wrist, and finally the elbow. It acts principally on the middle and terminal phalanges being extended mainly by the *Extensor carpi ulnaris*. It tends to separate the fingers as it extends them. The *Extensor digitorum* extends the little finger, and by its continued action assists in the extension of the thumb. The chief action of the *Abductor pollicis longus* is to carry the thumb of the hand. By its continued action it helps to extend and abduct the thumb; by their continued action they help to extend and abduct the thumb; by their continued action they help to extend and abduct the thumb. The *Extensor indicis proprius* extends the index finger, and by its continued action it helps to extend the wrist.

nsor muscles of the wrists and fingers, with its resulting "wrist drop," chronic lead poisoning. The Brachioradialis usually escapes in these s of the upper arm are paralyzed also. Usually the different Extensor affected; thus the thumb, or index or little finger, may be but slightly over rapidly while the Extensors of the other fingers or the wrist remain s is often shown by the Flexors of the fingers also, these muscles being tremor whenever extension of the fingers is attempted. Atrophy often poisoning.

On the hand are subdivided into three groups: (1) those of the thumb which arise from the radial side and produce the **thenar eminence**; (2) those which occupy the ulnar side and give rise to the **hypothenar eminence**; (3) those in the middle of the palm and between the metacarpal bones.

—Make a transverse incision across the front of the wrist, and a second longitudinal incision along the side of the fourth metacarpal bone; connect the two by a vertical incision in the middle of the palm through the centre of the middle finger. The volar, transverse, and dorsal carpal ligaments and the palmar aponeurosis should then be dissected.

Volar Carpal Ligament (*ligamentum carpi volare*).—The volar carpal ligament is the thickened band of antibrachial fascia which extends from the radius to the ulna over the Flexor tendons as they enter the wrist.

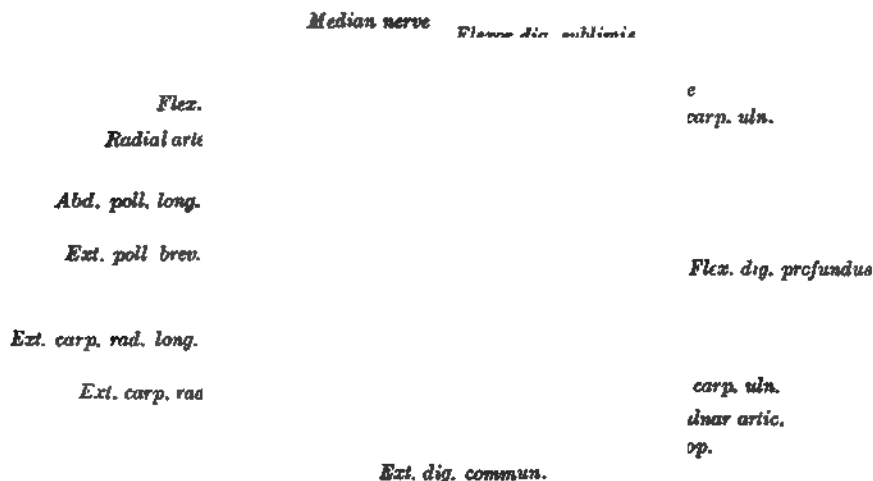

FIG. 528.—Transverse section across distal ends of radius and ulna.

Transverse Carpal Ligament (*ligamentum carpi transversum*; *anterior annular ligament*) (Figs. 528, 529).—The transverse carpal ligament is a strong, fibrous band, which arches over the carpus, converting the deep groove on the front of the carpal bones into a tunnel, through which the Flexor tendons of the digits and the median nerve pass. It is attached, medially, to the pisiform and the

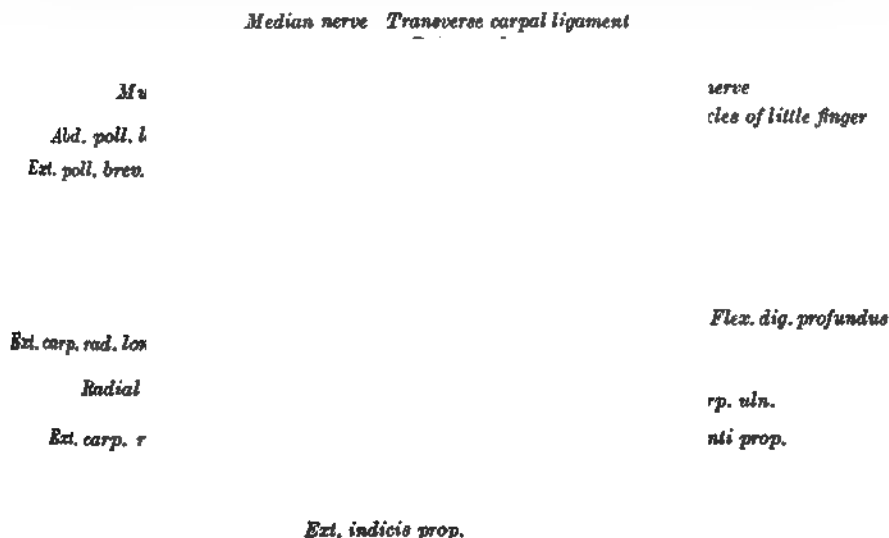

FIG. 529.—Transverse section across the wrist and digits.

hamulus of the hamate bone; laterally, to the tuberosity of the navicular, and to the medial part of the volar surface and the ridge of the greater multangular. It is continuous, above, with the volar carpal ligament; and below, with the palmar aponeurosis. It is crossed by the ulnar vessels and nerve, and the cutaneous branches of the median and ulnar nerves. At its lateral end is the tendon of the

MYOLOGY

or carpi radialis, which lies in the groove on the greater multangular between attachments of the ligament to the bone. On its volar surface the tendons of Palmaris longus and Flexor carpi ulnaris are partly *inserted*; below, it gives n to the short muscles of the thumb and little finger

FIG. 530.—The mucous sheaths of the tendons on the front of the wrist and digits.

The Mucous Sheaths of the Tendons on the Front of the Wrist.—Two sheaths envelop tendons as they pass beneath the transverse carpal ligament, one for the orcs digitorum sublimis and profundus, the other for the Flexor pollicis as (Fig. 530). They extend into the forearm for about 2.5 cm. above the sverse carpal ligament, and occasionally communicate with each other under

the ligament. The sheath which surrounds the *Flexores digitorum* extends downward about half-way along the metacarpal bones, where it ends in blind diverticula around the tendons to the index, middle, and ring fingers. It is prolonged on the tendons to the little finger and usually communicates with the mucous

FIG. 531.—The mucous sheaths of the tendons on the back of the wrist.

sheath of these tendons. The sheath of the tendon of the *Flexor pollicis longus* is continued along the thumb as far as the insertion of the tendon. The mucous sheaths enveloping the terminal parts of the tendons of the *Flexores digitorum* have been described on page 540.

Dorsal Carpal Ligament (*ligamentum carpi dorsale; posterior annular ligament*) (Figs. 528, 529).—The dorsal carpal ligament is a strong, fibrous band, extending obliquely downward and medialward across the back of the wrist, and consisting of part of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It is attached, *medially*, to the styloid process of the ulna and to the triangular and pisiform bones; *laterally*, to the lateral margin of the radius; and, in its passage across the wrist, to the ridges on the dorsal surface of the radius.

The Mucous Sheaths of the Tendons on the Back of the Wrist.—Between the dorsal carpal ligament and the bones six compartments are formed for the passage of tendons, each compartment having a separate mucous sheath. One is found in each of the following positions (Fig. 531): (1) on the lateral side of the styloid process, for the tendons of the Abductor pollicis longus and Extensor pollicis brevis; (2) behind the styloid process, for the tendons of the Extensores carpi radialis longus and brevis; (3) about the middle of the dorsal surface of the radius, for the tendon of the Extensor pollicis longus; (4) to the medial side of the latter, for the tendons of the Extensor digitorum communis and Extensor indicis proprius; (5) opposite the interval between the radius and ulna, for the Extensor digiti quinti proprius; (6) between the head and styloid process of the ulna, for the tendon of the Extensor carpi ulnaris. The sheaths lining these compartments extend from above the dorsal carpal ligament; those for the tendons of Abductor pollicis longus, Extensor brevis pollicis, Extensores carpi radialis, and Extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones, while the sheaths for Extensor communis digitorum, Extensor indicis proprius, and Extensor digiti quinti proprius are prolonged to the junction of the proximal and intermediate thirds of the metacarpus.

Palmar Aponeurosis (*aponeurosis palmaris; palmar fascia*) (Fig. 532).—The palmar aponeurosis invests the muscles of the palm, and consists of central, lateral, and medial portions.

The **central portion** occupies the middle of the palm, is triangular in shape, and of great strength and thickness. Its apex is continuous with the lower margin of the transverse carpal ligament, and receives the expanded tendon of the Palmaris longus. Its base divides below into four slips, one for each finger. Each slip gives off superficial fibres to the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpophalangeal articulations, and those to the fingers passing into the skin at the transverse fold at the bases of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the fibrous sheaths of the Flexor tendons. From the sides of these processes offsets are attached to the transverse metacarpal ligament. By this arrangement short channels are formed on the front of the heads of the metacarpal bones; through these the Flexor tendons pass. The intervals between the four slips transmit the digital vessels and nerves, and the tendons of the Lumbricales. At the points of division into the slips mentioned, numerous strong, transverse fasciculi bind the separate processes together. The central part of the palmar aponeurosis is intimately bound to the integument by dense fibroareolar tissue forming the superficial palmar fascia, and gives origin by its medial margin to the Palmaris brevis. It covers the superficial volar arch, the tendons of the Flexor muscles, and the branches of the median and ulnar nerves; and on either side it gives off a septum, which is continuous with the interosseous aponeurosis, and separates the intermediate from the collateral groups of muscles.

The **lateral and medial portions** of the palmar aponeurosis are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger; they are continuous with the central portion and with the fascia on the dorsum of the hand.

The **Superficial Transverse Ligament of the Fingers** is a thin band of transverse fasciculi (Fig. 532); it stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and medially to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass to their destinations.

artery and nerve

Ulnar art

FIG. 532.—The palmar aponeurosis.

Applied Anatomy.—The palmar aponeurosis is liable to undergo contraction, producing a very inconvenient deformity, known as *Dupuytren's contraction*. The ring and little fingers are most frequently implicated, but the others may also be involved. The proximal phalanx is flexed and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

Owing to their constant exposure to injury and septic influences, the fingers are very liable to become the seat of serious inflammatory mischief. To this inflammation the term *paronychia* or *whitlow* is given, and the affection may assume various degrees of severity. In the mildest cases the disease is confined to the superficial layer of the skin, and suppuration takes place beneath it. This is known as *subcuticular paronychia*, and is a comparatively simple condition, for an incision through the epidermis will at once relieve it. The only complication is that the pus may burrow under the nail, causing increased pain. A more severe condition is the *paronychia cellulosa*, in which the pulp of the end of the finger is involved. This is attended with intense throbbing pain, owing to the fact that the inflamed area is covered by thick and often horny epithelium, especially when the disease occurs in the laboring classes, as it so frequently does. In these cases, unless a timely incision is made, the inflammation is liable to involve the periosteum covering the phalanx, and *subperiosteal paronychia* is set up, which is followed by necrosis

MYOLOGY

part or the whole of the ungual phalanx. In other cases, the inflammation may involve the sheath of the Flexor tendons, and a *thecal paronychia* may result. The inflammation then spreads up the sheath; but the extent will depend upon the particular digit involved. From the description of the Flexor sheaths given above, it will be evident that inflammation of the mucous sheaths of the thumb and little finger may prove a far more formidable affection than that of the other three digits, because the sheaths of these two digits communicate with the mucous sheath which surrounds the Flexor tendons (p. 548), and the inflammation may spread into the palm of the hand and beneath the transverse carpal ligament into the forearm. In order to relieve these conditions, free and early incisions are necessary, and must be made with discrimination, in order to avoid wounding important structures. In the pulp of the finger—over the distal phalanx—the incision should be made in the middle line and down to the bone. In the rest of the finger, the incision should be made in the middle line over the phalanges, and over the interphalangeal joints. In the palm of the hand, incisions may be made either on the distal or proximal side of the superficial volar arch. On the distal side the incisions should be made over the metacarpal bones, preferably those of the index and middle finger. On the proximal side, the safest line of incision is along the radial side of the hypothenar eminence, over the ulnar artery and nerve medially, and the median nerve laterally. When suppuration has extended under the transverse carpal ligament, and incisions are required in the forearm, the positions in which they should be made are over the tendons of the Flexor digitorum profundus, between the median nerve and the ulnar artery, and over the tendon of the Flexor carpi ulnaris, between the radial artery and the tendon of the Flexor carpi radialis. Chronic inflammation of the common flexor sheath is occasionally met with, constituting a condition known as *compound palmar ganglion*; it presents an hour-glass outline, with a swelling at the wrist and another in the palm of the hand, and a constriction, corresponding to the transverse carpal ligament, between the two. The fluid can be forced from the one swelling into the other under the ligament, and when this is done, a creaking sensation is sometimes perceived, from the presence of "melon-seed" bodies in the interior of the ganglion.

	Adductor pollicis (transversus).

metacarpal lig.

FIG. 533.—The muscles of the thumb.

The **Abductor pollicis brevis** (*Abductor pollicis*) is a thin, flat muscle, placed directly beneath the integument. It arises from the transverse carpal ligament, the tuberosity of the navicular, and the ridge of the greater multangular,

frequently by two distinct slips. Running lateralward and downward, it is *inserted* by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb and the capsule of the metacarpophalangeal articulation.

The **Opponens pollicis** is a small, triangular muscle, placed beneath the preceding. It *arises* from the ridge on the greater multangular and from the transverse carpal ligament, passes downward and lateralward, and is *inserted* into the whole length of the metacarpal bone of the thumb on its radial side.

FIG. 534.—The muscles of the left hand. Palmar surface.

The **Flexor pollicis brevis** consists of two portions, lateral and medial. The lateral and more superficial portion *arises* from the lower border of the transverse

MYOLOGY

pal ligament and the lower part of the ridge on the greater multangular bone; passes along the radial side of the tendon of the Flexor pollicis longus, and, becoming tendinous, is *inserted* into the radial side of the base of the first phalanx of the thumb; in its tendon of insertion there is a sesamoid bone. The **medial deeper portion** of the muscle is very small, and *arises* from the ulnar side of the first metacarpal bone between the Adductor pollicis (obliquus) and the lateral head of the first Interosseous dorsalis, and is *inserted* into the ulnar side of the base of the first phalanx with the Adductor pollicis (obliquus). The medial part of the Flexor brevis pollicis is sometimes described as the **first Interosseous volaris**.

The **Adductor pollicis (obliquus)** (*Adductor obliquus pollicis*) *arises* by several heads from the capitate bone, the bases of the second and third metacarpals, the carpal ligaments, and the sheath of the tendon of the Flexor carpi radialis. In this origin the greater number of fibres pass obliquely downward and converge to a tendon, which, uniting with the tendons of the medial portion of the Flexor pollicis brevis and the transverse part of the Adductor, is *inserted* into the ulnar side of the base of the first phalanx of the thumb, a sesamoid bone being present in the tendon. A considerable fasciculus, however, passes more obliquely beneath the tendon of the Flexor pollicis longus to join the lateral portion of the Flexor brevis and the Abductor pollicis brevis.

The **Adductor pollicis (transversus)** (*Adductor transversus pollicis*) (Fig. 533) is the most deeply seated of this group of muscles. It is of a triangular form arising by a broad base from the lower two-thirds of the volar surface of the second metacarpal bone; the fibres converge, to be *inserted* with the medial part of the Flexor pollicis brevis and the Adductor pollicis (obliquus) into the ulnar side of the base of the first phalanx of the thumb.

Nerves.—The Abductor brevis, Opponens, and lateral head of the Flexor pollicis brevis are supplied by the sixth and seventh cervical nerves through the median nerve; the medial head of the Flexor brevis, and the Adductor, by the eighth cervical through the ulnar nerve.

Actions.—The Abductor pollicis brevis draws the thumb forward in a plane at right angles to that of the palm of the hand. The Abductor pollicis is the opponent of this muscle, and approximates the thumb to the palm. The Opponens pollicis flexes the metacarpal bone, i. e., draws medialward over the palm; the Flexor pollicis brevis flexes and adducts the proximal phalanx.

2. The Medial Volar Muscles (Figs. 533, 534).

Palmaris brevis.

Abductor digiti quinti.

Flexor digiti quinti brevis.

Opponens digiti quinti.

The **Palmaris brevis** is a thin, quadrilateral muscle, placed beneath the integument of the ulnar side of the hand. It *arises* by tendinous fasciculi from the transverse carpal ligament and palmar aponeurosis; the fleshy fibres are inserted into the skin on the ulnar border of the palm of the hand.

The **Abductor digiti quinti** (*Abductor minimi digiti*) is situated on the ulnar border of the palm of the hand. It *arises* from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and ends in a flat tendon, which divides into two parts; one is *inserted* into the ulnar side of the base of the first phalanx of the little finger; the other into the ulnar border of the aponeurosis of the Extensor digiti minimi proprius.

The **Flexor digiti quinti brevis** (*Flexor brevis minimi digiti*) lies on the same side as the preceding muscle, on its radial side. It *arises* from the convex surface of the hamulus of the hamate bone, and the volar surface of the transverse carpal ligament, and is *inserted* into the ulnar side of the base of the first phalanx of the little finger. It is separated from the Abductor, at its origin, by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor, when present, is usually, of large size.

The **Opponens digiti quinti** (*Opponens minimi digiti*) (Fig. 533) is of a triangular form, and placed immediately beneath the preceding muscles. It *arises* from the convexity of the hamulus of the hamate bone, and contiguous portion of the transverse carpal ligament; it is inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

Nerves.—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The Abductor and Flexor digiti quinti brevis abduct the little finger from the ring finger and assist in flexing the proximal phalanx. The Opponens digiti quinti draws forward the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the ulnar side of the palm.

3. The Intermediate Muscles.

Lumbricales.

Interossei.

The **Lumbricales** (Fig. 534) are four small fleshy fasciculi, associated with the tendons of the Flexor digitorum profundus. The first and second *arise* from the radial sides and volar surfaces of the tendons of the index and middle fingers respectively; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and opposite the metacarpophalangeal articulation is *inserted* into the tendinous expansion of the Extensor digitorum communis covering the dorsal aspect of the finger.

FIG. 535.—The Interossei dorsales of left hand.

FIG. 536.—The Interossei volares of left hand

The **Interossei** (Figs. 535, 536) are so named from occupying the intervals between the metacarpal bones, and are divided into two sets, a dorsal and a volar.

The **Interossei dorsales** (*Dorsal interossei*) are *four* in number, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, each *arising* by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeuroses

MYOLOGY

the tendons of the *Extensor digitorum communis*. Between the double origin of each of these muscles is a narrow triangular interval; through the first of these the radial artery passes; through each of the other three a perforating branch from the deep volar arch is transmitted.

The **first** or **Abductor indicis** is larger than the others. It is flat, triangular in shape, and arises by two heads, separated by a fibrous arch for the passage of the radial artery from the dorsum to the palm of the hand. The lateral head arises from the proximal half of the ulnar border of the first metacarpal bone; the medial head, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The **second** and **third** are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The **fourth** is inserted into the ulnar side of the ring finger.

The **Interossei volares** (*Palmar interossei*), three in number, are smaller than the *Interossei dorsales*, and placed upon the volar surfaces of the metacarpal bones, one between each of them. Each arises from the entire length of the metacarpal bone of one finger, and is inserted into the side of the base of the first phalanx and the neurotic expansion of the *Extensor communis* tendon to the same finger.

The **first** arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The **second** arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The **third** arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account may be seen that each finger is provided with two *Interossei*, with the exception of the little finger, in which the *Abductor* takes the place of one of the pair.

As already mentioned (p. 554), the medial head of the *Flexor pollicis brevis* is sometimes described as the *Interosseus volaris primus*.

Nerves.—The two lateral *Lumbricales* are supplied by the sixth and seventh cervical nerves, through the third and fourth digital branches of the median nerve; the two medial *Lumbricales* and all the *Interossei* are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. The third *Lumbricalis* frequently receives a twig from the median.

Actions.—The *Interossei volares* adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the *Interossei dorsales* abduct the fingers from that line.

In addition to this the *Interossei*, in conjunction with the *Lumbricales*, flex the first phalanges at the metacarpophalangeal joints, and extend the second and third phalanges in consequence of their insertions into the expansions of the *Extensor tendons*. The *Extensor digitorum communis* is believed to act almost entirely on the first phalanges.

Applied Anatomy.—In considering the actions of the various muscles upon fractures of the hand and extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the middle of the clavicle (Fig. 537) is usually attended with considerable displacement of the lateral fragment, which is drawn downward and medialward, and at the same time adducted, so that its lateral end is carried forward and its medial end backward.

The displacement is produced as follows: the lateral fragment is drawn downward by the weight of the arm, the *Trapezius* not being able to support this. It is drawn medialward by the *Latissimus dorsi* and *Pectoralis minor*, possibly assisted by the *Pectoralis major* and *Latissimus dorsi*; is rotated on an axis drawn through its own centre by the *Serratus anterior*, which causes the scapula to rotate on the wall of the chest, and carries the acromion and the end of the lateral portion of the clavicle forward, and so carries the medial end of the lateral portion backward. When the causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The lateral fragment is to be drawn lateralward, and, together with the scapula, raised to level with the medial fragment, and retained in that position.

Fracture of the acromial end of the clavicle, between the conoid and trapezoid ligaments, if slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold the portions of the bone in apposition. Fracture, also, of the *sternal end*, medial to the costoclavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the acromion is usually caused by violence applied to the upper and lateral part of the shoulder. There is great displacement; the lateral fragment being drawn downward by the weight of the arm, and rotated forward and medialward, so that it forms a right angle with the shaft of the bone.

Fracture of the *surgical neck of the humerus* (Fig. 538) is very common. It is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment remains in its place under the coracoacromial ligament; the lower is drawn medialward by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely from the side of the chest by the Deltoideus, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm lateralward and downward. To counteract the opposing muscles, and to keep the fragments in position, a cone-shaped pad should be placed in the axilla, and the arm bandaged to the side by a broad roller passed around the chest in such a manner that the elbow is carried slightly forward, so as to throw the upper end of the lower fragment backward and lateralward toward the head of the bone. The whole is then covered with a carefully moulded gutta-percha or poroplastic shoulder cap.

FIG 537 —Fracture of the middle of the clavicle.

FIG 538 —Fracture of the surgical neck of the humerus.

In fracture of the *body of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoideus, there is also considerable deformity, the upper fragment being drawn medialward by the first-mentioned muscles, and the lower fragment upward and lateralward by the Deltoideus. Shortening of the limb results, with a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture take place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

In fracture of the *body of the humerus* immediately below the insertion of the Deltoideus the amount of deformity depends greatly upon the direction of the fracture. If it occur in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forward; but in oblique fracture, the combined actions of the Biceps brachii and Brachialis in front and the Triceps brachii behind draw upward the lower fragment, causing it to glide over the upper, either backward or forward, according to the direction of the fracture. Simple extension reduces the deformity, and the application of a shoulder cap and splints to the arm will retain the fragments in apposition.

Fracture of the *humerus* (Fig. 539) immediately above the condyles deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backward. If the direction of the fracture is oblique, from above, downward and forward, the lower fragment is drawn upward by the Brachialis and Biceps brachii in front, and the Triceps brachii behind; and at the same time is drawn backward behind the upper fragment by the Triceps brachii. This fracture may be diagnosed from dislocation, by the increased mobility, the existence of crepitus, and the fact that the deformity is remedied by extension, but is reproduced on the

VOLOGY

is of importance in distinguishing this form of injury from cases where the injury has been produced by falls on the hand and forward, causing a considerable prominence of the olecranon beneath the tendon of the Triceps brachii. In this case the detached fragment is displaced upward, by the action of the Triceps; the prominence of the elbow is consequently lost, and the joint, which is much increased on flexing the forearm, is more or less, the power of extending the forearm. The fragments are brought together; but if for some reason this operation is not possible, the joint may be held by strapping or a figure-of-eight bandage, and the patient is to relax the Triceps brachii. Massage and passive motion are of use in the treatment of ankylosis. Union, when wiring is not resorted to, is usually complete.

28.

FIG. 540.—Fracture of the olecranon

In the case of a fracture of the olecranon, the upper fragment is strongly supinated by the Biceps brachii and Supinator, and flexed by the Biceps brachii; the lower fragment is strongly pronated by the Pronators. Thus there is extreme displacement of the fragments. In the treatment of a fracture of the olecranon the arm must be put up in a position of great impairment of the movements of the elbow. If the upper fragment is drawn upward by the Biceps brachii and medialward by the Pronator teres, into a position midway between pronation and supination, and a degree of fulness in the upper half of the forearm is thus produced. The lower fragment is drawn downward toward the ulna and pronated by the Pronator quadratus; at the same time, the Brachioradialis, by elevating the styloid process, into which it is inserted, will serve to depress the upper end of the lower fragment still more toward the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination. The fracture is then easily reduced by extension from the elbow. A bandage should be applied on both sides of the forearm from the elbow to the wrist.

The upper fragment retains its usual position, but the lower fragment is displaced downward and forward, producing a well-marked depression at the dorsal and volar surfaces of the forearm. The fracture is at the wrist and elbow. The forearm should be flexed, pronated and supinated, and well-padded splints applied.

In fracture of the *bodies of the radius and ulna together*, the lower fragments are drawn upward, sometimes forward, sometimes backward, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on either the dorsal or volar surface of the forearm. At the same time the lower fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation. The upper fragment of the radius is drawn upward and medialward by the Biceps brachii and Pronator teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

FIG. 542.—Fracture of the lower end of the radius.

In fracture of the *lower end of the radius* (Fig. 542) the displacement produced is very considerable, and bears some resemblance to dislocation of the carpus backward, from which it should be carefully distinguished. The lower fragment is displaced backward and upward, but this displacement is due to the force of the blow driving the portion of the bone into this position, and not to any muscular influence. The upper fragment projects forward, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the volar surface of the forearm, immediately above the carpus, from the Flexor tendons being thrust forward. This fracture may be distinguished from dislocation by the relative positions of the styloid processes of the radius and ulna (the former of which is displaced upward in fracture) and by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected. The age of the patient will assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in a position of adduction toward the ulnar side.

THE MUSCLES AND FASCIÆ OF THE LOWER EXTREMITY.

The muscles of the lower extremity are subdivided into groups corresponding with the different regions of the limb.

| II. Muscles of the Thigh. | IV. Muscles of the Foot. |

I. THE MUSCLES AND FASCIÆ OF THE ILIAC REGION (Fig. 543).

Psoas major.

Psoas minor.

Iliacus.

Dissection.—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

The **Fascia Covering the Psoas and Iliacus** is thin above, and becomes gradually thicker below as it approaches the inguinal ligament.

The **portion covering the Psoas** is thickened *above* to form the medial lumbo-costal arch, which stretches from the transverse process of the first lumbar vertebra to the body of the second. *Medially*, it is attached by a series of arched processes

to the intervertebral fibrocartilages, and prominent margins of the bodies of the vertebrae, and to the upper part of the sacrum; the intervals left, opposite the constricted portions of the bodies, transmit the lumbar arteries and veins and filaments of the sympathetic trunk. *Laterally*, above the crest of the ilium, it is continuous with the fascia covering the front of the Quadratus lumborum (see page 510), while below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The portions investing the Iliacus (*fascia iliaca; iliac fascia*) is connected, *laterally* to the whole length of the inner lip of the iliac crest; and *medially*, to the linea terminalis of the lesser pelvis, where it is continuous with the periosteum. At the iliopectineal eminence it receives the tendon of insertion of the Psoas minor, when that muscle exists. Lateral to the femoral vessels it is intimately connected to the posterior margin of the inguinal ligament, and is continuous with the transversalis fascia. Immediately lateral to the femoral vessels the iliac fascia is prolonged backward and medialward from the inguinal ligament as a band, the *iliopectineal fascia*, which is attached to the iliopectineal eminence. This fascia divides the space between the inguinal ligament and the hip bone into two lacunæ or compartments, the medial of which transmits the femoral vessels, the lateral the Psoas major and Iliacus and the femoral nerve. Medial to the vessels the iliac fascia is attached to the pectineal line behind the inguinal aponeurotic falx, where it is again continuous with the transversalis fascia. On the thigh the fasciæ of the Iliacus and Psoas form a single sheet termed the *iliopectineal fascia*. Where the external iliac vessels pass into the thigh, the fascia descends behind them, forming the posterior wall of the femoral sheath. The portion of the iliopectineal fascia which passes behind the femoral vessels is also attached to the pectineal line beyond the limits of the attachment of the inguinal aponeurotic falx; at this part it is continuous with the pectineal fascia. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus are behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The **Psoas major** (*Psoas magnus*) (Fig. 543) is a long fusiform muscle placed on the side of the lumbar region of the vertebral column and brim of the lesser pelvis. It *arises* (1)

FIG. 543.—Muscles of the iliac and anterior femoral regions.

from the anterior surfaces of the bases and lower borders of the transverse processes of all the lumbar vertebræ; (2) from the sides of the bodies and the corresponding intervertebral fibrocartilages of the last thoracic and all the lumbar vertebræ by five slips, each of which is attached to the adjacent upper and lower margins of two vertebræ, and to the intervertebral fibrocartilage; (3) from a series of tendinous arches which extend across the constricted parts of the bodies of the lumbar vertebræ between the previous slips; the lumbar arteries and veins, and filaments from the sympathetic trunk pass beneath these tendinous arches. The muscle proceeds downward across the brim of the lesser pelvis, and diminishing gradually in size, passes beneath the inguinal ligament and in front of the capsule of the hip-joint and ends in a tendon; the tendon receives nearly the whole of the fibres of the Iliacus and is *inserted* into the lesser trochanter of the femur. A large bursa which may communicate with the cavity of the hip-joint, separates the tendon from the pubis and the capsule of the joint.

Relations.—In the abdomen the Psoas major is in relation by its *anterior surface* with the medial lumbocostal arch, the fascia covering the muscle, the extraperitoneal fat and peritoneum, the kidney, Psoas minor, renal vessels, ureter, spermatic vessels, and genitofemoral nerve. In front of the right Psoas is the inferior vena cava and the terminal portion of the ileum, and in front of the left the iliac colon. By its *posterior surface* it is in relation with the transverse processes of the lumbar vertebræ, and the Quadratus lumborum. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *medial side*, the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the gangliated trunk of the sympathetic, and the lumbar lymph glands; with the inferior vena cava on the right, and the aorta on the left side, and along the brim of the pelvis with the external iliac artery.

In the thigh it is in relation, in *front*, with the fascia lata; *behind*, with the capsule of the hip-joint, from which it is separated by a bursa; by its *medial border*, with the Pectineus and medial circumflex femoral artery, and also with the femoral artery, which slightly overlaps it; by its *lateral border*, with the femoral nerve and Iliacus.

The **Psoas minor** (*Psoas parvus*) is a long slender muscle, placed in front of the Psoas major. It *arises* from the sides of the bodies of the twelfth thoracic and first lumbar vertebræ and from the fibrocartilage between them. It ends in a long flat tendon which is *inserted* into the pectineal line and iliopectineal eminence, and, by its lateral border, into the iliac fascia. This muscle is often absent.

The **Iliacus** is a flat, triangular muscle, which fills the iliac fossa. It *arises* from the upper two-thirds of this fossa, and from the inner lip of the iliac crest; behind, from the anterior sacroiliac and the iliolumbar ligaments, and base of the sacrum; in front, it reaches as far as the anterior superior and anterior inferior iliac spines, and the notch between them. The fibres converge to be inserted into the lateral side of the tendon of the Psoas major, some of them being prolonged on to the body of the femur for about 2.5 cm. below and in front of the lesser trochanter.¹

Relations.—Within the abdomen the Iliacus is in relation by its *anterior surface* with the iliac fascia, which separates the muscle from the extraperitoneal fat and peritoneum, and with the lateral femoral cutaneous nerve; on the right side, with the cecum; on the left side, with the iliac colon; by its *posterior surface*, with the iliac fossa; by its *medial border*, with the Psoas major and femoral nerve.

In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus femoris, Sartorius, and profunda femoris artery; behind, with the capsule of the hip-joint, a bursa common to it and the Psoas major being interposed.

Nerves.—The Psoas major is supplied by branches of the second and third lumbar nerve; the Psoas minor by a branch of the first lumbar nerve; and the Iliacus by branches of the second and third lumbar nerves through the femoral nerve.

Actions.—The Psoas major, acting from above, flexes the thigh upon the pelvis, being assisted by the Iliacus; acting from below, with the femur fixed, it bends the lumbar portion of the vertebral column forward and to its own side, and then, in conjunction with the Iliacus, tilts the pelvis forward. When the muscles of both sides are acting from below, they serve to maintain the

¹ The Psoas major and iliacus are sometimes regarded as a single muscle named the *Iliopsoas*.

to the intervertebral fibrocartilages, and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum; the intervals left, opposite the constricted portions of the bodies, transmit the lumbar arteries and veins and filaments of the sympathetic trunk. *Laterally*, above the crest of the ilium, it is continuous with the fascia covering the front of the *Quadratus lumborum* (see page 510), while below the crest of the ilium it is continuous with the fascia covering the *Iliacus*.

The portions investing the *Iliacus* (*fascia iliaca*; *iliac fascia*) is connected, *laterally* to the whole length of the inner lip of the iliac crest; and *medially*, to the *linea terminalis* of the lesser pelvis, where it is continuous with the *periosteum*. At the *iliopectineal eminence* it receives the tendon of insertion of the *Psoas minor*, when that muscle exists. Lateral to the femoral vessels it is intimately connected to the posterior margin of the inguinal ligament, and is continuous with the *transversalis fascia*. Immediately lateral to the femoral vessels the iliac fascia is prolonged backward and medialward from the inguinal ligament as a band, the *iliopectineal fascia*, which is attached to the *iliopectineal eminence*. This fascia divides the space between the inguinal ligament and the hip bone into two *lacunæ* or compartments, the medial of which transmits the femoral vessels, the lateral the *Psoas major* and *Iliacus* and the femoral nerve. Medial to the vessels the iliac fascia is attached to the *pectineal line* behind the inguinal *aponeurotic falx*, where it is again continuous with the *transversalis fascia*. On the thigh the fasciæ of the *Iliacus* and *Psoas* form a single sheet termed the *iliopectineal fascia*. Where the external iliac vessels pass into the thigh, the fascia descends behind them, forming the posterior wall of the femoral sheath. The portion of the *iliopectineal fascia* which passes behind the femoral vessels is also attached to the *pectineal line* beyond the limits of the attachment of the inguinal *aponeurotic falx*; at this part it is continuous with the *pectineal fascia*. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus are behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The *Psoas major* (*Psoas magnus*) (Fig. 543) is a long fusiform muscle placed on the side of the lumbar region of the vertebral column and brim of the lesser pelvis. It arises (1)

FIG. 543.—Muscles of the iliac and anterior femoral regions.

from the anterior surfaces of the bases and lower borders of the transverse processes of all the lumbar vertebræ; (2) from the sides of the bodies and the corresponding intervertebral fibrocartilages of the last thoracic and all the lumbar vertebræ by five slips, each of which is attached to the adjacent upper and lower margins of two vertebræ, and to the intervertebral fibrocartilage; (3) from a series of tendinous arches which extend across the constricted parts of the bodies of the lumbar vertebræ between the previous slips; the lumbar arteries and veins, and filaments from the sympathetic trunk pass beneath these tendinous arches. The muscle proceeds downward across the brim of the lesser pelvis, and diminishing gradually in size, passes beneath the inguinal ligament and in front of the capsule of the hip-joint and ends in a tendon; the tendon receives nearly the whole of the fibres of the Iliacus and is *inserted* into the lesser trochanter of the femur. A large bursa which may communicate with the cavity of the hip-joint, separates the tendon from the pubis and the capsule of the joint.

Relations.—In the abdomen the Psoas major is in relation by its *anterior surface* with the medial lumbocostal arch, the fascia covering the muscle, the extraperitoneal fat and peritoneum, the kidney, Psoas minor, renal vessels, ureter, spermatic vessels, and genitofemoral nerve. In front of the right Psoas is the inferior vena cava and the terminal portion of the ileum, and in front of the left the iliac colon. By its *posterior surface* it is in relation with the transverse processes of the lumbar vertebræ, and the Quadratus lumborum. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *medial side*, the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the gangliated trunk of the sympathetic, and the lumbar lymph glands; with the inferior vena cava on the right, and the aorta on the left side, and along the brim of the pelvis with the external iliac artery.

In the thigh it is in relation, in *front*, with the fascia lata; *behind*, with the capsule of the hip-joint, from which it is separated by a bursa; by its *medial border*, with the Pectineus and medial circumflex femoral artery, and also with the femoral artery, which slightly overlaps it; by its *lateral border*, with the femoral nerve and Iliacus.

The **Psoas minor** (*Psoas parvus*) is a long slender muscle, placed in front of the Psoas major. It *arises* from the sides of the bodies of the twelfth thoracic and first lumbar vertebræ and from the fibrocartilage between them. It ends in a long flat tendon which is *inserted* into the pectineal line and iliopectineal eminence, and, by its lateral border, into the iliac fascia. This muscle is often absent.

The **Iliacus** is a flat, triangular muscle, which fills the iliac fossa. It *arises* from the upper two-thirds of this fossa, and from the inner lip of the iliac crest; behind, from the anterior sacroiliac and the iliolumbar ligaments, and base of the sacrum; in front, it reaches as far as the anterior superior and anterior inferior iliac spines, and the notch between them. The fibres converge to be inserted into the lateral side of the tendon of the Psoas major, some of them being prolonged on to the body of the femur for about 2.5 cm. below and in front of the lesser trochanter.¹

Relations.—Within the abdomen the Iliacus is in relation by its *anterior surface* with the iliac fascia, which separates the muscle from the extraperitoneal fat and peritoneum, and with the lateral femoral cutaneous nerve; on the right side, with the cecum; on the left side, with the iliac colon; by its *posterior surface*, with the iliac fossa; by its *medial border*, with the Psoas major and femoral nerve.

In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus femoris, Sartorius, and profunda femoris artery; behind, with the capsule of the hip-joint, a bursa common to it and the Psoas major being interposed.

Nerves.—The Psoas major is supplied by branches of the second and third lumbar nerve; the Psoas minor by a branch of the first lumbar nerve; and the Iliacus by branches of the second and third lumbar nerves through the femoral nerve.

Actions.—The Psoas major, acting from above, flexes the thigh upon the pelvis, being assisted by the Iliacus; acting from below, with the femur fixed, it bends the lumbar portion of the vertebral column forward and to its own side, and then, in conjunction with the Iliacus, tilts the pelvis forward. When the muscles of both sides are acting from below, they serve to maintain the

¹ The Psoas major and iliacus are sometimes regarded as a single muscle named the *Iliopsoas*.

erect posture by supporting the vertebral column and pelvis upon the femora, or in continued action bend the trunk and pelvis forward, as in raising the trunk from the recumbent posture.

The Psoas minor is a tensor of the iliac fascia.

Applied Anatomy.—There is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseofibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscles into the thigh.

Abscess within the sheath of the Psoas major (*psoas abscess*) is generally due to tuberculous caries of the bodies of the lower thoracic or the lumbar vertebræ. When the disease is in the thoracic region, the matter tracks down the posterior mediastinal cavity in front of the bodies of the vertebræ, and, passing beneath the medial lumbocostal arch, enters the sheath of the Psoas, down which it travels as far as the pelvic brim; it then gets beneath the iliac portion of the fascia, and fills up the iliac fossa. In consequence of the attachment of the fascia to the arcuate line, it rarely finds its way into the lesser pelvis, but passes by a narrow opening under the inguinal ligament into the thigh, lateral to the femoral vessels. It thus follows that a psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under the inguinal ligament, and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, the matter finds its way directly into the substance of the Psoas. The muscular fibres are destroyed, and the nerves contained in the abscess are isolated and exposed in its interior; the iliac vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All psoas abscesses do not, however, pursue this course; the matter may leave the sheath of the muscle above the crest of the ilium, and tracking backward may point in the loin (*lumbar abscess*); or it may point above the inguinal ligament in the inguinal region; or it may follow the course of the branches of the hypogastric vessels into the lesser pelvis, and, passing through the greater sciatic foramen, discharge itself on the back of the thigh.

Dissection.—To expose the muscles and fasciæ in this region, make an incision along the inguinal ligament, from the anterior superior spine of the ilium to the spine of the pubis; a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciæ should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia and femoral triangle, the incisions for the dissection of which are marked out in Fig. 544.

Superficial Fascia.—The superficial fascia forms a continuous layer over the whole of the thigh; it consists of areolar tissue containing in its meshes much fat, and may be separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymph glands, the great saphenous vein, and several smaller vessels. The superficial layer is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous stratum, best marked on the medial side of the great saphenous vein and below the inguinal ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below the inguinal ligament. It covers the *fossa ovalis* (*saphenous opening*), being closely united to its circumference, and is connected to the sheath of the femoral vessels. The

portion of fascia covering this fossa is perforated by the great saphenous vein and by numerous blood and lymphatic vessels, hence it has been termed the *fascia cribrosa*, the openings for these vessels having been likened to the holes in a sieve. A large subcutaneous bursa is found in the superficial fascia over the patella.

Deep Fascia.—The deep fascia of the thigh is named, from its great extent, the *fascia lata*; it constitutes an investment for the whole of this region of the limb, but varies in thickness in different parts. Thus, it is thicker in the upper and lateral part of the thigh, where it receives a fibrous expansion from the *Glutaeus maximus*, and where the *Tensor fasciae latae* is inserted between its layers; it is very thin behind and at the upper and medial part, where it covers the *Adductor* muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the *Biceps femoris* laterally, from the *Sartorius* medially, and from the *Quadriceps femoris* in front. The *fascia lata* is attached, above and behind, to the back of the sacrum and coccyx; laterally, to the iliac crest; in front, to the inguinal ligament, and to the superior ramus of the pubis; and medially, to the inferior ramus of the pubis, to the inferior ramus and tuberosity of the ischium, and to the lower border of the sacrotuberous ligament. From its attachment to the iliac crest it passes down over the *Glutaeus medius* to the upper border of the *Glutaeus maximus*, where it splits into two layers, one passing superficial to and the other beneath this muscle; at the lower border of the muscle the two layers reunite. Laterally, the *fascia lata* receives the greater part of the tendon of insertion of the *Glutaeus maximus*, and becomes proportionately thickened. The portion of the *fascia lata* attached to the front part of the iliac crest, and corresponding to the origin of the *Tensor fasciae latae*, extends down the lateral side of the thigh as two layers, one superficial to and the other beneath this muscle; at the lower end of the muscle these two layers unite and form a strong band, having first received the insertion of the muscle. This band is continued downward, under the name of the *iliotibial band* (*tractus iliotibialis*) and is attached to the lateral condyle of the tibia. The part of the *iliotibial band* which lies beneath the *Tensor fasciae latae* is prolonged upward to join the lateral part of the capsule of the hip-joint. Below, the *fasciae lata* is attached to all the prominent points around the knee-joint, viz., the condyles of the femur and tibia, and the head of the fibula. On either side of the patella it is strengthened by transverse fibres from the lower parts of the *Vasti*, which are attached to and support this bone. Of these the lateral are the stronger, and are continuous with the *iliotibial band*. The deep surface of the *fascia lata* gives off two strong intermuscular septa, which are attached to the whole length of the *linea aspera* and its prolongations above and below; the lateral and stronger one, which extends from the insertion of the *Glutaeus maximus* to the lateral condyle, separates the *Vastus lateralis* in front from the short head of the *Biceps femoris* behind, and gives

FIG. 544.—Dissection of lower extremity. Front view.

MYOLOGY

these muscles; the medial and thinner one separates the Vastus medialis from the Adductores and Pectineus. Besides these there are numerous septa separating the individual muscles, and enclosing each in a distinct

fossa ovalis (*saphenous opening*) (Fig. 545).—At the upper and medial end of the thigh, a little below the medial end of the inguinal ligament, is a large aperture in the fascia lata; it transmits the great saphenous vein, and the accompanying vessels, and is termed the **fossa ovalis**. The fascia cribrosa, formed by the structures passing through the opening, closes the aperture and is moved to expose it. The fascia lata in this part of the thigh is consisting of a superficial and a deep portion.

FIG. 545.—The fossa ovalis.

The **superficial portion** of the fascia lata is the part on the lateral side of the thigh, extending from the crest and anterior superior spine of the ilium, along the length of the inguinal ligament, and to the pectineal line in connection with the lacunar ligament. From the tubercle of the pubis it is reflected laterally, as an arched margin, the **falciform margin**, forming the lateral boundary of the fossa ovalis; this margin overlies and is adherent to the sheath of the femoral vessels: to its edge is attached the fascia lata. Its upward and medial prolongation of the falciform margin is named the **superior cornu**; its downward and medial prolongation, the **inferior cornu**. The inferior cornu is continued, and is continuous behind the great saphenous vein with the

The **deep portion** is situated on the medial side of the fossa ovalis, and at the lower margin of the fossa is continuous with the superficial portion; traced upward, it covers the Pectineus, Adductor longus, and Gracilis, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the iliopectineal fascia, and is attached to the pectineal line.

From this description it may be observed that the superficial portion of the fascia lata lies in front of the femoral vessels, and the deep portion behind them, so that an apparent aperture exists between the two, through which the great saphenous passes to join the femoral vein.

The **Tensor fasciae latae** (*Tensor fasciae femoris*) arises from the anterior part of the outer lip of the iliac crest; from the outer surface of the anterior superior iliac spine, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius; and from the deep surface of the fascia lata. It is *inserted* between the two layers of the iliotibial band of the fascia lata about the junction of the middle and upper thirds of the thigh.

The **Sartorius**, the longest muscle in the body, is narrow and ribbon-like; it *arises* by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it. It passes obliquely across the upper and anterior part of the thigh, from the lateral to the medial side of the limb, then descends vertically, as far as the medial side of the knee, passing behind the medial condyle of the femur to end in a tendon. This curves obliquely forward and expands into a broad aponeurosis, which is *inserted*, in front of the Gracilis and Semitendinosus, into the upper part of the medial surface of the body of the tibia, nearly as far forward as the anterior crest. The upper part of the aponeurosis is curved backward over the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset, from its upper margin, blends with the capsule of the knee-joint, and another from its lower border, with the fascia on the medial side of the leg.

Relations.—The relations of this muscle to the femoral artery are important, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the lateral side of a triangular space, the *femoral (Scarpa's) triangle*, the medial side of which is formed by the medial border of the Adductor longus, and the base, directed upward, by the inguinal ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh the femoral artery is contained in the *adductor (Hunter's) canal*, on the roof of which the Sartorius lies.

The **Quadriceps femoris** (*Quadriceps extensor*) includes the four remaining muscles on the front of the thigh. It is the great extensor muscle of the leg, forming a large fleshy mass which covers the front and sides of the femur. It is subdivided into separate portions, which have received distinctive names. One occupying the middle of the thigh, and connected above with the ilium, is called from its straight course the **Rectus femoris**. The other three lie in immediate connection with the body of the femur, which they cover from the trochanters to the condyles. The portion on the lateral side of the femur is termed the **Vastus lateralis**; that covering the medial side, the **Vastus medialis**; and that in front, the **Vastus intermedius**.

The **Rectus femoris** is situated in the middle of the front of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It *arises* by two tendons: one, the anterior or straight, from the anterior inferior iliac spine; the other, the posterior or reflected, from a groove above the brim of the acetabulum. The two unite at an acute angle, and spread into an aponeurosis which is prolonged downward on the anterior surface of the muscle, and from this the muscular fibres arise. The muscle ends in a broad and thick aponeurosis which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is *inserted* into the base of the patella.

The **Vastus lateralis** (*Vastus externus*) is the largest part of the Quadriceps femoris. It *arises* by a broad aponeurosis, which is attached to the upper part of the intertrochanteric line, to the anterior and inferior borders of the greater trochanter, to the lateral lip of the gluteal tuberosity, and to the upper half of the lateral lip of the linea aspera; this aponeurosis covers the upper three-fourths of the muscle, and from its deep surface many fibres take origin. A few additional fibres arise from the tendon of the Glutæus maximus, and from the lateral intermuscular septum between the Vastus lateralis and short head of the Biceps femoris. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the deep surface of the lower part of the muscle: this aponeurosis becomes contracted and thickened into a flat tendon inserted into the lateral border of the patella, blending with the Quadriceps femoris tendon, and giving an expansion to the capsule of the knee-joint.

The Vastus medialis and Vastus intermedius appear to be inseparably united, but when the Rectus femoris has been reflected a narrow interval will be observed extending upward from the medial border of the patella between the two muscles, and the separation may be continued as far as the lower part of the intertrochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus medialis** (*Vastus internus*) *arises* from the lower half of the intertrochanteric line, the medial lip of the linea aspera, the upper part of the medial supracondylar line, the tendons of the Adductor longus and the Adductor magnus and the medial intermuscular septum. Its fibres are directed downward and forward, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is *inserted* into the medial border of the patella and the Quadriceps femoris tendon, an expansion being sent to the capsule of the knee-joint.

The **Vastus intermedius** (*Crureus*) *arises* from the front and lateral surfaces of the body of the femur in its upper two-thirds and from the lower part of the lateral intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the Quadriceps femoris tendon.

The **tendons** of the different portions of the Quadriceps unite at the lower part of the thigh, so as to form a single strong tendon, which is inserted into the base of the patella, some few fibres passing over it to blend with the ligamentum patellæ. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps; and the ligamentum patellæ, which is continued from the apex of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle, the medial and lateral patellar retinacula (see p. 439) being expansions from its borders. A bursa, which usually communicates with the cavity of the knee-joint, is situated between the femur and the portion of the Quadriceps tendon above the patella; another is interposed between the tendon and the upper part of the front of the tibia; and a third, the **prepatellar bursa**, is placed over the patella itself.

The **Articularis genu** (*Subcrureus*) is a small muscle, usually distinct from the Vastus intermedius, but occasionally blended with it; it *arises* from the anterior surface of the lower part of the body of the femur, and is inserted into the upper part of the synovial membrane of the knee-joint. It sometimes consists of several separate muscular bundles.

Nerves.—The Tensor fasciæ latae is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through the femoral nerve.

Actions.—The Tensor fasciæ latae is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct the thigh and to rotate it inward. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur; and by means of the iliotibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Glutæus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next abducts and rotates the thigh outward. When the knee is bent, the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inward. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists

in rotating the pelvis. The Quadriceps femoris extends the leg upon the thigh. The Rectus femoris assists the Psoas major and Iliacus in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh be fixed it will flex the pelvis. The Vastus medialis draws the patella medialward as well as upward.

Applied Anatomy.—A few fibres of the Rectus femoris are occasionally ruptured from severe strain. This accident is especially liable to occur during the games of football and baseball. The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus stands out as is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps femoris may be torn away from its insertion into the patella; or the ligamentum patellae may be ruptured about 2.5 cm. above the bone. This accident is caused in the same manner as fracture of the patella by muscular action, viz., by a violent muscular effort to prevent falling while the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

2. The Medial Femoral Muscles.

Gracilis.
Pectineus.

Adductor longus.
Adductor brevis.

Adductor magnus.

Dissection.—These muscles are at once exposed by removing the fascia from the forepart and inner side of the thigh. The limb should be abducted, so as to render the muscles tense and easier of dissection.

The **Gracilis** (Fig. 543) is the most superficial muscle on the medial side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It *arises* by a thin aponeurosis from the anterior margins of the lower half of the symphysis pubis and the upper half of the pubic arch. The fibres run vertically downward, and end in a rounded tendon, which passes behind the medial condyle of the femur, curves around the medial condyle of the tibia, where it becomes flattened, and is *inserted* into the upper part of the medial surface of the body of the tibia, below the condyle. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. At its insertion the tendon is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. It is separated from the tibial collateral ligament of the knee-joint, by a bursa common to it and the tendon of the Semitendinosus.

The **Pectineus** (Fig. 543) is a flat, quadrangular muscle, situated at the anterior part of the upper and medial aspect of the thigh. It *arises* from the pectineal line, and to a slight extent from the surface of bone in front of it, between the iliopectineal eminence and tubercle of the pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downward, backward, and lateralward, to be inserted into a rough line leading from the lesser trochanter to the linea aspera.

Relations.—It is in relation by its *anterior surface* with the fascia lata, which separates it from the femoral vessels and great saphenous vein; by its *posterior surface*, with the capsule of the hip-joint, the Adductor brevis, Obturator externus, and the anterior branch of the obturator nerve; by its *lateral border*, with the Psoas major and the medial femoral circumflex vessels; by its *medial border*, with the margin of the Adductor longus.

The **Adductor longus** (Fig. 546), the most superficial of the three Adductores, is a triangular muscle, lying in the same plane as the Pectineus. It *arises* by a flat, narrow tendon, from the front of the pubis, at the angle of junction of the crest with the symphysis; and soon expands into a broad fleshy belly. This passes downward, backward, and lateralward, and is *inserted*, by an aponeurosis, into the linea aspera, between the Vastus medialis and the Adductor magnus, with both of which it is usually blended.

Relations.—It is in relation by its *anterior surface* with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; by its *posterior surface*, with the

MYOLOGY

anterior branch of the obturator nerve, and near its artery and vein; by its *lateral border*, with the Pectineus;

The **Adductor brevis** (Fig. 546) is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and *arises* by a narrow origin from the outer surfaces of the superior and inferior rami of the pubis, between the Gracilis and Obturator externus. Its fibres, passing backward, lateralward, and downward, are *inserted*, by an aponeurosis, into the line leading from the lesser trochanter to the linea aspera and into the upper part of the linea aspera, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—It is in relation by its *anterior surface* with the Pectineus, Adductor longus, profunda femoris artery, and anterior branch of the obturator nerve; by its *posterior surface*, with the Adductor magnus, and posterior branch of the obturator nerve; by its *lateral border*, with the medial femoral circumflex artery, the Obturator externus, and conjoined tendon of the Psoas major and Iliacus; by its *medial border*, with the Gracilis and Adductor magnus. It is pierced near its insertion by the second, or first and second, perforating branches of the profunda femoris artery.

The **Adductor magnus** (Fig. 546) is a large triangular muscle, situated on the medial side of the thigh. It *arises* from a small part of the inferior ramus of the pubis, from the inferior ramus of the ischium, and from the outer margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the pubis are short, horizontal in direction, and are inserted into the rough line leading from the greater trochanter to the linea aspera, medial to the Gluteus maximus;¹ those from the ramus of the ischium are directed downward and lateralward with different degrees of obliquity, to be *inserted*, by means of a broad aponeurosis, into the linea aspera and the upper part of its medial prolongation below. The medial portion of the muscle, composed principally of the fibres arising from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and end about the lower third of the thigh in a rounded tendon which is inserted into the adductor tubercle on the medial condyle of

¹ as a separate muscle—the *Adductor minimus*—which is situated

the femur, and is connected by a fibrous expansion to the line leading upward from the tubercle to the linea aspera. At the *insertion* of the muscle, there is a series of osseoponeurotic openings, formed by tendinous arches attached to the bone. The upper four openings are small, and give passage to the perforating branches of the profunda femoris artery. The lowest is of large size, and transmits the femoral vessels to the popliteal fossa.

Relations.—It is in relation by its *anterior surface* with the Pectineus, Adductores brevis and longus, the femoral and profunda vessels, and the posterior branch of the obturator nerve; by its *posterior surface*, with the sciatic nerve, the Glutaeus maximus, Biceps femoris, Semitendinosus, and Semimembranosus. Its *superior border* lies parallel with the Quadratus femoris, the medial femoral circumflex artery passing between them. Its *medial border* is in relation with the Gracilis, Sartorius, and fascia lata.

Nerves.—The three Adductores and the Gracilis are supplied by the third and fourth lumbar nerves through the obturator nerve; the Adductor magnus receiving an additional branch from the sacral plexus through the sciatic. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the femoral nerve, and by the third lumbar through the accessory obturator when this latter exists. Occasionally it receives a branch from the obturator nerve.¹

Actions.—The Pectineus and three Adductores adduct the thigh powerfully; they are especially used in horse exercise, the sides of the saddle being grasped between the knees by the contraction of these muscles. In consequence of the obliquity of their insertions into the linea aspera, they rotate the thigh outward, assisting the external Rotators, and when the limb has been abducted, they draw it medialward, carrying the thigh across that of the opposite side. The Pectineus and Adductores brevis and longus assist the Psoas major and Iliacus in flexing the thigh upon the pelvis. In progression, all these muscles assist in drawing forward the lower limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inward; it is also an adductor of the thigh. If the lower extremities be fixed, these muscles, taking their fixed points below, may act upon the pelvis, serving to maintain the body in an erect posture; or, if their action be continued, flex the pelvis forward upon the femur.

Applied Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon may be ruptured by suddenly gripping the saddle. Occasionally, especially in cavalry soldiers, the tendon becomes ossified, constituting the *rider's bone*.

3. The Muscles of the Gluteal Region (Fig. 548).

Glutaeus maximus.
Glutaeus medius.
Glutaeus minimus.
Piriformis.

Obturator internus.
Gemellus superior.
Gemellus inferior.
Quadratus femoris.

Obturator externus.

Dissection (Fig. 547).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum, and thence downward to the tip of the coccyx, and carry a second incision from that point obliquely downward and outward to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The **Glutaeus maximus**, the most superficial muscle in the gluteal region, is a broad and thick fleshy mass of a quadrilateral shape, and forms the prominence of the nates. Its large size is one of the most characteristic features of the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. The muscle is remarkably coarse in structure, being made up of fasciculi lying parallel with one another and collected together into large bundles separated by fibrous septa. It *arises* from the posterior gluteal line of the ilium, and the rough portion of bone including the crest, immediately above and behind it; from the posterior surface of the lower part of the sacrum and the

¹ The Pectineus may consist of two incompletely separated strata; the lateral or dorsal stratum, which is constant, is supplied by a branch from the femoral nerve, or in the absence of this branch by the accessory obturator nerve, the medial or ventral stratum, when present, is supplied by the obturator nerve.—A. M. Paterson. *Journal of Anatomy and Physiology*, xxvi, 43.

MYOLOGY

; from the aponeurosis of the Sacrospinalis, the sacrotuberous fascia (gluteal aponeurosis) covering the Glutæus medius, directed obliquely downward and lateralward; those forming the anterior portion of the muscle, together with the superficial fibres of the Glutæus medius, are inserted in a thick tendinous lamina, which passes across the greater trochanter, and is inserted into the iliotibial band of the fascia lata; the deeper portion of the muscle are inserted into the gluteal tuberosity of the ischium, the Glutæus lateralis and Adductor magnus.

There are usually found in relation with the deep surface of this muscle. One, the Glutæus minimus, and generally multilocular, separates it from the greater trochanter; a second, often wanting, is situated on the tuberosity of the ischium; a third is found between the tendon of the Glutæus medius and that of the Vastus lateralis.

*Dissection of
gluteal region.*

Back of thigh.

Gluteal space.

Back of leg.

Back of foot.

*Lower extremity.
View.*

Relations.—The Glutæus maximus is in relation by its superficial surface with a thin fascia which separates it from the subcutaneous tissue; by its deep surface, from above downward, with the ilium, sacrum, coccyx, and sacrotuberous ligament, part of the Glutæus medius, Piriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, greater trochanter, the origins of the Biceps femoris, Semitendinosus, Semimembranosus, and the Adductor magnus. The superficial part of the superior gluteal artery reaches the deep surface of the muscle by passing between the Piriformis and the Glutæus medius; the inferior gluteal and internal pudendal vessels and the sciatic, pudendal, and lateral femoral cutaneous nerves, and muscular branches from the sacral plexus, issue from the pelvis below the Piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also found under cover of the lower part of the muscle. Its upper border is thin, and connected with the Glutæus medius by the gluteal aponeurosis. Its lower border is free and prominent, and is crossed by the fold of the nates.

Dissection.—Divide the Glutæus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Glutæus medius and Rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outward; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The **Glutæus medius** is a broad, thick, radiating muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Glutæus maximus, its anterior two-thirds by the Glutæus minimus, which separates it from the superficial fascia and inserts it from the outer surface of the ilium between the iliac crest and the anterior gluteal line above, and the anterior gluteal line below; it also arises from the aponeurosis covering its outer surface. The fibres converge to a tendon, which is inserted into the oblique ridge which runs down the lateral surface of the greater trochanter. A bursa is found between the muscle from the surface of the trochanter over which

The **Glutæus minimus**, the smallest of the three Glutæi, is placed immediately below the Glutæus medius. It is fan-shaped, arising from the outer surface of the ilium,

between the anterior and inferior gluteal lines, and behind, from the margin of the greater sciatic notch. The fibres converge to the deep surface of a radiated aponeurosis, and this ends in a tendon which is inserted into an impression on the anterior border of the greater trochanter, and gives an expansion to the capsule of the hip-joint. A bursa is interposed between the tendon and the greater trochanter. Between the Glutæus medius and Glutæus minimus are the deep branches of the superior gluteal vessels and the superior gluteal nerve. The deep surface of the Glutæus minimus is in relation with the reflected tendon of the Rectus femoris and the capsule of the hip-joint.

The **Piriformis** is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Glutæus medius. It is situated partly within the pelvis against its posterior wall, and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and to the grooves leading from the foramina: a few fibres also arise from the margin of the greater sciatic foramen, and from the anterior surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the greater trochanter behind, but often partly blended with, the common tendon of the Obturator internus and Gemelli.

Relations. - Within the pelvis the Piriformis is in relation by its anterior surface with the rectum (especially on the left side), the sacral plexus of nerves, and branches of the hypogastric vessels; and by its posterior surface

h
 L
 Semite
 L
 mem

FIG. 548.--Muscles of the gluteal and posterior femoral regions.

MYOLOGY

the sacrum. *Outside the pelvis*, its *anterior surface* is in contact with the posterior surface of the ischium and capsule of the hip-joint; and its *posterior surface*, with the Glutæus maximus; its *upper border* is in relation with the Glutæus medius, and the superior gluteal vessels and nerve; its *lower border*, with the Gemellus superior and Coccygeus, the inferior gluteal and pudendal vessels, and the sciatic, posterior femoral cutaneous, and pudendal and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles. The muscle is frequently pierced by the common peroneal nerve.

Obturator Membrane (Fig. 549).—The obturator membrane is a thin fibrous sheet, which almost completely closes the obturator foramen. Its fibres are arranged in crossing bundles mainly transverse in direction; the uppermost bundle is attached to the obturator tubercles and completes the obturator canal for the passage of the obturator vessels and nerve. The membrane is attached to the sharp margin of the obturator foramen except at its lower lateral angle, where it is fixed to the pelvic surface of the inferior ramus of the ischium, *i. e.*, within the margin. The obturator muscles are connected with this membrane.

*nphysia
rubia*

FIG. 549.—The obturator membrane.

Section.—The next muscle, as well as the origin of the Piriformis, can only be seen when the viscus is divided and the viscera removed.

Obturator Internus is situated partly within the lesser pelvis, and partly behind the hip-joint. It *arises* from the inner surface of the antero-lateral wall of the pelvis, where it surrounds the greater part of the obturator foramen, attached to the inferior rami of the pubis and ischium, and at the side to the surface of the hip bone below and behind the pelvic brim, reaching from the part of the greater sciatic foramen above and behind to the obturator foramen below and in front. It also arises from the pelvic surface of the obturator foramen except in the posterior part, from the tendinous arch which completes the foramen for the passage of the obturator vessels and nerve, and to a slight extent from the obturator fascia, which covers the muscle. The fibres converge rapidly toward the lesser sciatic foramen, and end in four or five tendinous bands, which are found

on the deep surface of the muscle; these bands are reflected at a right angle over the grooved surface of the ischium between its spine and tuberosity. This bony surface is covered by smooth cartilage, which is separated from the tendon by a bursa, and presents one or more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite into a single flattened tendon, which passes horizontally across the capsule of the hip-joint, and, after receiving the attachments of the Gemelli, is *inserted* into the forepart of the medial surface of the greater trochanter above the trochanteric fossa. A bursa, narrow and elongated in form, is usually found between the tendon and the capsule of the hip-joint; it occasionally communicates with the bursa between the tendon and the ischium.

Relations.—*Within the pelvis*, this muscle is in relation, by its *antero-lateral surface*, with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *pelvic surface*, with the obturator fascia, and the origin of the Levator ani, and with the internal pudendal vessels and pudendal nerve which cross it. This surface forms the lateral boundary of the ischiorectal fossa. *Outside the pelvis*, the muscle is covered by the Glutaeus maximus, crossed by the sciatic nerve, and rests on the back part of the hip-joint. When the tendon of the Obturator internus emerges from the lesser sciatic foramen it is overlapped both in front and behind by the two Gemelli which form a muscular canal for it; near its insertion the Gemelli pass in front of the tendon and form a groove in which it lies.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus which is received into a groove between them.

The **Gemellus superior**, the smaller of the two, *arises* from the outer surface of the spine of the ischium, blends with the upper part of the tendon of the Obturator internus, and is *inserted* with it into the medial surface of the greater trochanter. It is sometimes wanting.

The **Gemellus inferior** *arises* from the upper part of the tuberosity of the ischium, immediately below the groove for the Obturator internus tendon. It blends with the lower part of the tendon of the Obturator internus, and is *inserted* with it into the medial surface of the greater trochanter.

The **Quadratus femoris** is a flat, quadrilateral muscle, between the Gemellus inferior and the upper margin of the Adductor magnus; it is separated from the latter by the terminal branches of the medial femoral circumflex vessels. It *arises* from the upper part of the external border of the tuberosity of the ischium, and is *inserted* into the upper part of the linea quadrata—that is, the line which extends vertically downward from the intertrochanteric crest. A bursa is often found between the front of this muscle and the lesser trochanter.

The **Obturator externus** (Fig. 550) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It *arises* from the margin of bone immediately around the medial side of the obturator foramen, viz., from the rami of the pubis, and the inferior ramus of the ischium; it also arises from the medial two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres springing from the pubic arch extend on to the inner surface of the bone, where they obtain a narrow origin between the margin of the foramen and the attachment of the obturator membrane. The fibres converge and pass backward, lateralward, and upward, and end in a tendon which runs across the back of the neck of the femur and lower part of the capsule of the hip-joint and is *inserted* into the trochanteric fossa of the femur. The obturator vessels lie between the muscle and the obturator membrane; the anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it.

Nerves.—The Glutaeus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve; the Glutaei medius and minimus by the fourth and

fifth lumbar and first sacral nerves through the superior gluteal; the Piriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerves; the Gemellus superior and Obturator internus by the first, second, and third sacral nerves, and the Obturator externus by the third and fourth lumbar nerves through the obturator.

pine

FIG. 550.—The Obturator externus.

Actions.—When the Glutaeus maximus takes its fixed point from the pelvis, it extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the trunk upon the head of the femur; this is especially obvious in standing on one leg. Its most powerful action is to cause the body to regain the erect position after stooping, by drawing the pelvis backward, being assisted in this action by the Biceps femoris, Semitendinosus, and Semimembranosus. The Glutaeus maximus is a tensor of the fascia lata, and by its connection with the iliotibial band steadies the femur on the articular surfaces of the tibia during standing, when the Extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and external rotator of the limb. The Glutaei medius and minimus abduct the thigh, when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciae latae. Their anterior fibres, by drawing the greater trochanter forward, rotate the thigh inward, in which action they are also assisted by the Tensor fasciae latae. The remaining muscles are powerful external rotators of the thigh. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotators ceases, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outward.

4. The Posterior Femoral Muscles (Hamstring Muscles) (Fig. 548).

Biceps femoris.

Semitendinosus.

Semimembranosus.

Dissection (Fig. 547).—Make a vertical incision along the middle of the back of the thigh, from the lower fold of the buttock to about three inches below the back of the knee-joint, and there connect it with a transverse incision, carried from the inner to the outer side of the leg. Make a third incision transversely at the junction of the middle with the lower third of the thigh. The integument having been removed from the back of the knee, and the boundaries of the popliteal fossa having been examined, the removal of the integument from the remaining part of the thigh should be continued, when the fascia and muscles of this region will be exposed.

The **Biceps femoris** (*Biceps*) is situated on the posterior and lateral aspect of the thigh. It has two heads of origin; one, the **long head**, arises from the lower and inner impression on the back part of the tuberosity of the ischium, by a tendon common to it and the Semitendinosus, and from the lower part of the sacrotuberous ligament; the other, the **short head**, arises from the lateral lip of the linea aspera,

between the Adductor magnus and Vastus lateralis, extending up almost as high as the insertion of the Glutaeus maximus; from the lateral prolongation of the linea aspera to withing 5 cm. of the lateral condyle; and from the lateral inter-muscular septum. The fibres of the long head form a fusiform belly, which passes obliquely downward and lateralward across the sciatic nerve to end in an aponeurosis which covers the posterior surface of the muscle, and receives the fibres of the short head; this aponeurosis becomes gradually contracted into a tendon, which is *inserted* into the lateral side of the head of the fibula, and by a small slip into the lateral condyle of the tibia. At its insertion the tendon divides into two portions, which embrace the fibular collateral ligament of the knee-joint. From the posterior border of the tendon a thin expansion is given off to the fascia of the leg. The tendon of insertion of this muscle forms the lateral hamstring; the common peroneal nerve descends along its medial border.

The **Semitendinosus**, remarkable for the great length of its tendon of insertion, is situated at the posterior and medial aspect of the thigh. It *arises* from the lower and medial impression on the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps femoris; it also arises from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about 7.5 cm. from their origin. The muscle is fusiform and ends a little below the middle of the thigh in a long round tendon which lies along the medial side of the popliteal fossa; it then curves around the medial condyle of the tibia and passes over the tibial collateral ligament of the knee-joint, from which it is separated by a bursa, and is *inserted* into the upper part of the medial surface of the body of the tibia, nearly as far forward as its anterior crest. At its insertion it gives off from its lower border a prolongation to the deep fascia of the leg and lies behind the tendon of the Sartorius, and below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscle.

The **Semimembranosus**, so called from its membranous tendon of origin, is situated at the back and medial side of the thigh. It *arises* by a thick tendon from the upper and outer impression on the tuberosity of the ischium, above and lateral to the Biceps femoris and Semitendinosus, and is *inserted* into the groove on the back of the medial condyle of the tibia. The tendon of origin expands into an aponeurosis, which covers the upper part of the anterior surface of the muscle; from this aponeurosis muscular fibres arise, and converge to another aponeurosis which covers the lower part of the posterior surface of the muscle and contracts into the tendon of insertion. The tendon of insertion gives off certain fibrous expansions: one, of considerable size, passes upward and lateralward to be *inserted* into the back part of the lateral condyle of the femur, forming part of the oblique popliteal ligament of the knee-joint; a second is continued downward to the fascia which covers the Popliteus muscle; while a few fibres join the tibial collateral ligament of the joint and the fascia of the leg. The muscle overlaps the upper part of the popliteal vessels.

The tendons of insertion of the two preceding muscles form the medial hamstrings.

Nerves.—The muscles of this region are supplied by the fourth and fifth lumbar and the first, second, and third sacral nerves; the nerve to the short head of the Biceps femoris is derived from the common peroneal, the other muscles are supplied through the tibial nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps femoris in consequence of its oblique direction rotates the leg slightly outward; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inward, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur, and to draw the trunk directly backward, as in raising it from the stooping position or in feats of strength, when the body is thrown backward in the form of an arch. As already indicated on page 383, complete flexion of the hip cannot be effected unless the knee-joint is also flexed, on account of the shortness of the hamstring muscles.

Applied Anatomy.—In disease of the knee-joint, contraction of the hamstring tendons is a frequent complication; this causes flexion of the leg, and a partial dislocation of the tibia back-

ward, with a slight degree of rotation outward, probably due to the action of the Biceps femoris. The hamstring tendons occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the muscles, or from contracture of the ligamentous and other tissues surrounding the joint, the result of disease. The relation of the common peroneal nerve, which lies in close apposition to the medial border of the tendon of the Biceps femoris, must always be borne in mind in dividing this tendon, and a free incision with exposure of the tendon, before division, is the safer proceeding.

III. THE MUSCLES AND FASCIAE OF THE LEG.

The muscles of the leg may be divided into three groups: anterior, posterior, and lateral.

1. The Anterior Crural Muscles (Fig. 551).

Tibialis anterior.

Extensor hallucis longus.

Extensor digitorum longus.

Peronaeus tertius.

Dissection (Fig. 543).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

Deep Fascia (*fascia cruris*).—The deep fascia of the leg forms a complete investment to the muscles, and is fused with the periosteum over the subcutaneous surfaces of the bones. It is continuous *above* with the fascia lata, and is attached around the knee to the patella, the ligamentum patellae, the tuberosity and condyles of the tibia, and the head of the fibula. *Behind*, it forms the popliteal fascia, covering in the popliteal fossa; here it is strengthened by transverse fibres, and perforated by the small saphenous vein. It receives an expansion from the tendon of the Biceps femoris laterally, and from the tendons of the Sartorius, Gracilis, Semitendinosus, and Semimembranosus medially; in *front*, it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and malleolus of the fibula; below, it is continuous with the transverse crural and lacinate ligaments. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anterior and Extensor digitorum longus; but thinner behind, where it covers the Gastrocnemius and Soleus. It gives off from its deep surface, on the lateral side of the leg, two strong intermuscular septa, the **anterior** and **posterior peroneal septa**, which enclose the Peronaei longus and brevis, and separate them from the muscles of the anterior and posterior crural regions, and several more slender processes which enclose the individual muscles in each region. A broad transverse intermuscular septum, called the **deep transverse fascia of the leg**, intervenes between the superficial and deep posterior crural muscles.

Dissection.—Remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left entire. Commence the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscle fibres.

The **Tibialis anterior** (*Tibialis anticus*) is situated on the lateral side of the tibia; it is thick and fleshy above, tendinous below. It *arises* from the lateral condyle and upper half or two-thirds of the lateral surface of the body of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor digitorum longus. The fibres run vertically downward, and end in a tendon, which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the most medial compartments of the transverse and cruciate crural

ligaments, it is *inserted* into the medial and under surface of the first cuneiform bone, and the base of the first metatarsal bone. This muscle overlaps the anterior tibial vessels and deep peroneal nerve in the upper part of the leg.

The **Extensor hallucis longus** (*Extensor proprius hallucis*) is a thin muscle, situated between the Tibialis anterior and the Extensor digitorum longus. It *arises* from the anterior surface of the fibula for about the middle two-fourths of its extent, medial to the origin of the Extensor digitorum longus; it also *arises* from the interosseous membrane to a similar extent. The anterior tibial vessels and deep peroneal nerve lie between it and the Tibialis anterior. The fibres pass downward, and end in a tendon, which occupies the anterior border of the muscle, passes through a distinct compartment in the cruciate crural ligament, crosses from the lateral to the medial side of the anterior tibial vessels near the bend of the ankle, and is *inserted* into the base of the distal phalanx of the great toe. Opposite the metatarsophalangeal articulation, the tendon gives off a thin prolongation on either side, to cover the surface of the joint. An expansion from the medial side of the tendon is usually inserted into the base of the proximal phalanx.

The **Extensor digitorum longus** is a penniform muscle, situated at the lateral part of the front of the leg. It *arises* from the lateral condyle of the tibia; from the upper three-fourths of the anterior surface of the body of the fibula; from the upper part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anterior on the medial, and the Peronei on the lateral side. Between it and the Tibialis anterior are the upper portions of the anterior tibial vessels and deep peroneal nerve. The tendon passes under the transverse and cruciate crural ligaments in company with the Peroneus tertius, and divides into four slips, which run forward on the dorsum of the foot, and are *inserted* into the second and third phalanges of the four lesser toes. The tendons to the second, third, and fourth toes are each joined, opposite the metatarsophalangeal articulation, on the lateral side by a tendon of the Extensor digitorum brevis. The tendons are inserted in the following manner: each receives a fibrous expansion from the Interossei and Lumbricalis, and then spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into

the
xl
'nt

FIG. 351.—Muscles of the front of the leg.

three slips—an intermediate, which is inserted into the base of the second phalanx; and two collateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onward, to be inserted into the base of the third phalanx.

The **Peronæus tertius** is a part of the Extensor digitorum longus, and might be described as its fifth tendon. The fibres belonging to this tendon *arise* from the lower third or more of the anterior surface of the fibula; from the lower part of the interosseous membrane; and from an intermuscular septum between it and the Peronæus brevis. The tendon, after passing under the transverse and cruciate crural ligaments in the same canal as the Extensor digitorum longus, is *inserted* into the dorsal surface of the base of the metatarsal bone of the little toe. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the deep peroneal nerve.

Actions.—The Tibialis anterior and Peronæus tertius are the direct flexors of the foot at the ankle-joint; the former muscle, when acting in conjunction with the Tibialis posterior, raises the medial border of the foot, *i. e.*, inverts the foot; and the latter, acting with the Peronæi brevis and longus, raises the lateral border of the foot, *i. e.*, everts the foot. The Extensor digitorum longus and Extensor hallucis longus extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed points from below, in the erect posture, these muscles serve to fix the bones of the leg in the perpendicular position, and give increased length to the ankle-joint.

2. The Posterior Crural Muscles.

Dissection (Fig. 547).—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal fossa to the heel, connecting it below by a transverse incision tending between the two malleoli; the flaps of integument being removed, the fascia and muscles could be examined.

The muscles of the back of the leg are subdivided into two groups—superficial and deep. Those of the superficial group constitute a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct relation to his erect attitude and his mode of progression.

The Superficial Group (Fig. 552).

Gastrocnemius.

Soleus.

Plantaris.

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It *arises* by two heads, which are connected to the condyles of the femur by strong, flat tendons. The **medial and larger head** takes its origin from a depression at the upper and back part of the medial condyle and from the adjacent part of the femur. The **lateral head** *arises* from an impression on the side of the lateral condyle and from the posterior surface of the femur immediately above the lateral part of the condyle. Both heads, also, *arise* from the subjacent part of the capsule of the knee. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs. From the anterior surfaces of these tendinous expansions, muscular fibres are given off; those of the medial head being thicker and extending lower than those of the lateral. The fibres unite at an angle in the middle line of the muscle in a tendinous raphé, which expands into a broad aponeurosis on the anterior surface of the muscle, and into this the remaining fibres are inserted. The aponeurosis, gradually contracting, unites with the tenon of the Soleus, and forms with it the tendo calcaneus.

Relations.—The Gastrocnemius is in relation by its *superficial surface* with the fascia of the leg, which separates it from the small saphenous vein and the peroneal anastomotic, medial sural taneous, and sural nerves; the common peroneal nerve crosses the lateral head, lying partly under cover of the Biceps femoris. Its *deep surface* is in relation with the oblique popliteal ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and tibial nerve. In

front of the tendon of the medial head is a bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the lateral head sometimes contains a sesamoid fibrocartilage or bone, where it plays over the corresponding condyle; and one is occasionally found in the tendon of the medial head.

The **Soleus** is a broad flat muscle situated immediately in front of the Gastrocnemius. It *arises* by tendinous fibres from the back of the head of the fibula, and from the upper third of the posterior surface of the body of the bone; from the popliteal line, and the middle third of the medial border of the tibia; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, in front of which the popliteal vessels and tibial nerve run. The fibres end in an aponeurosis which covers the posterior surface of the muscle, and, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo calcaneus.

Relations.—By its *superficial surface* it is in relation with the Gastrocnemius and Plantaris; by its *deep surface*, with the Flexor digitorum longus, Flexor hallucis longus, Tibialis posterior, and posterior tibial vessels and nerve, from which it is separated by the deep transverse fascia of the leg.

The Gastrocnemius and Soleus together form a muscular mass which is occasionally described as the **Triceps surae**; its tendon of insertion is the tendo calcaneus.

Tendo Calcaneus (*tendo Achillis*).—The tendo calcaneus, the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest in the body. It is about 15 cm. long, and begins near the middle of the leg, but receives fleshy fibres on its anterior surface, almost to its lower end. Gradually becoming contracted below, it is inserted into the middle part of the posterior surface of the calcaneus, a bursa being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is about 4 cm. above its insertion. It is covered by the fascia and the integument, and is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its lateral side, but superficial to it, is the small saphenous vein.

The **Plantaris** is placed between the Gastrocnemius and Soleus. It *arises* from the lower part of the lateral prolongation of the linea aspera, and from the oblique popliteal ligament of the knee-joint. It forms a small fusiform belly, from 7 to 10 cm. long, ending in a long slender tendon which crosses obliquely between the two muscles of the calf, and runs along the medial border of the tendo calcaneus, to be *inserted* with it into the posterior part of the calcaneus. This muscle is sometimes double, and at other times wanting. Occasionally, its tendon is lost in the lacinate ligament, or in the fascia of the leg.

Nerves.—The Gastrocnemius and Soleus are supplied by the first and second sacral nerves, and the Plantaris by the fourth and fifth lumbar and first sacral nerves, through the tibial nerve.

Actions.—The muscles of the calf are the chief extensors of the foot at the ankle-joint. They possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking, these muscles raise the heel from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forward. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot and prevents the body from falling forward. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia, assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which in some of the lower animals is continued over the calcaneus to be inserted into the plantar aponeurosis. In man it is an accessory to the Gastrocnemius, extending the ankle if the foot be free, or bending the knee if the foot be fixed.

The Deep Group (Fig. 553).

Popliteus.

Flexor hallucis longus.

Flexor digitorum longus.

Tibialis posterior.

Dissection.—Detach the Soleus from its attachment to the fibula and tibia, and turn it downward, when the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

MYOLOGY

The deep transverse fascia of the leg is a transversely
between the superficial and deep muscles of the

muscle of
longus
tibia

of leg.

FIG. 553.—Muscles of the back of the leg.
Deep layer.

As it is connected to the margins of the tibia and
the Popliteus, it is thick and dense, and receives
from the Semimembranosus; it is thinner in the middle

of the leg; but *below*, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the lacinate ligament.

Dissection.—This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The **Popliteus** is a thin, flat, triangular muscle, which forms the lower part of the floor of the popliteal fossa. It *arises* by a strong tendon about 2.5 cm. long, from a depression at the anterior part of the groove on the lateral condyle of the femur, and to a small extent from the oblique popliteal ligament of the knee-joint; and is *inserted* into the medial two-thirds of the triangular surface above the popliteal line on the posterior surface of the body of the tibia, and into the tendinous expansion covering the surface of the muscle.

Relations.—The tendon of the muscle is covered by that of the Biceps femoris and by the fibular collateral ligament of the knee-joint; it grooves the posterior border of the lateral meniscus, and is invested by the synovial membrane of the knee-joint. The fascia covering the muscle separates it from the Gastrocnemius, Plantaris, popliteal vessels, and tibial nerve. The deep surface of the muscle is in contact with the oblique popliteal ligament of the knee-joint and the back of the tibia.

The **Flexor hallucis longus** is situated on the fibular side of the leg. It *arises* from the inferior two-thirds of the posterior surface of the body of the fibula, with the exception of 2.5 cm. at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the Peronaei, laterally, and from the fascia covering the Tibialis posterior, medially. The fibres pass obliquely downward and backward, and end in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon lies in a groove which crosses the posterior surface of the lower end of the tibia, the posterior surface of the talus, and the under surface of the sustentaculum tali of the calcaneus; in the sole of the foot it runs forward between the two heads of the Flexor hallucis brevis, and is *inserted* into the base of the last phalanx of the great toe. The grooves on the talus and calcaneus, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals, lined by a mucous sheath. As the tendon passes forward in the sole of the foot, it is situated above, and crosses from the lateral to the medial side of the tendon of the Flexor digitorum longus, to which it is connected by a fibrous slip.

Relations.—The Flexor hallucis longus is in relation by its *superficial surface* with the Soleus and tendo calcaneus, from which it is separated by the deep transverse fascia; by its *deep surface*, with the fibula, Tibialis posterior, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; by its *lateral border*, with the Peronaei; by its *medial border*, with the Tibialis posterior and posterior tibial vessels and tibial nerve.

The **Flexor digitorum longus** is situated on the tibial side of the leg. At its origin it is thin and pointed, but it gradually increases in size as it descends. It *arises* from the posterior surface of the body of the tibia, from immediately below the popliteal line to within 7 or 8 cm. of its lower extremity, medial to the tibial origin of the Tibialis posterior; it also *arises* from the fascia covering the Tibialis posterior. The fibres end in a tendon, which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the medial malleolus, in a groove, common to it and the Tibialis posterior, but separated from the latter by a fibrous septum, each tendon being contained in a special compartment lined by a separate mucous sheath. It passes obliquely forward and lateralward, superficial to the deltoid ligament of the ankle-joint, into the sole of the foot (Fig. 557), where it crosses below the tendon of the Flexor hallucis longus, and receives from it a strong tendinous slip. It then expands and is joined by the Quadratus plantae, and finally divides into four tendons, which are *inserted* into the bases of the last phalanges of the second, third, fourth, and fifth toes, each tendon passing through

an opening in the corresponding tendon of the Flexor digitorum brevis opposite the base of the first phalanx.

Relations.—In the leg this muscle is in relation by its *superficial surface* with the posterior tibial vessels and tibial nerve, and the deep transverse fascia which separates it from the Soleus; by its *deep surface*, with the tibia and Tibialis posterior. In the foot, it is covered by the Abductor hallucis and Flexor digitorum brevis, and crosses superficial to the Flexor hallucis longus.

The **Tibialis posterior** (*Tibialis posticus*) lies between the two preceding muscles, and is the most deeply seated of the muscles on the back of the leg. It begins above by two pointed processes, separated by an angular interval through which the anterior tibial vessels pass forward to the front of the leg. It *arises* from the whole of the posterior surface of the interosseous membrane, excepting its lowest part; from the lateral portion of the posterior surface of the body of the tibia, between the commencement of the popliteal line above and the junction of the middle and lower thirds of the body below; and from the upper two-thirds of the medial surface of the fibula; some fibres also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles. In the lower fourth of the leg its tendon passes in front of that of the Flexor digitorum longus and lies with it in a groove behind the medial malleolus, but enclosed in a separate sheath; it next passes under the laciniata and over the deltoid ligament into the foot, and then beneath the plantar calcaneonavicular ligament. The tendon contains a sesamoid fibrocartilage, as it runs under the plantar calcaneonavicular ligament. It is *inserted* into the tuberosity of the navicular bone, and gives off fibrous expansions, one of which passes backward to the sustentaculum tali of the calcaneus, others forward and lateralward to the three cuneiforms, the cuboid, and the bases of the second, third, and fourth metatarsal bones.

Relations.—The Tibialis posterior is in relation by its *superficial surface* with the Soleus, from which it is separated by the deep transverse fascia, the Flexor digitorum longus, the posterior tibial vessels and tibial nerve, and the peroneal vessels; by its *deep surface*, with the interosseous membrane, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the fourth and fifth lumbar and first sacral nerves, the Flexor digitorum longus and Tibialis posterior by the fifth lumbar and first sacral, and the Flexor hallucis longus by the fifth lumbar and the first and second sacral nerves, through the tibial nerve.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inward. It is especially called into action at the beginning of the act of bending the knee, inasmuch as it produces the slight inward rotation of the tibia which is essential in the early stage of this movement. The Tibialis posterior is a direct extensor of the foot at the ankle-joint; acting in conjunction with the Tibialis anterior, it turns the sole of the foot upward and medialward, *i. e.*, inverts the foot, antagonizing the Peronei, which turn it upward and lateralward (evert it). In the sole of the foot the tendon of the Tibialis posterior lies directly below the plantar calcaneonavicular ligament, and is therefore an important factor in maintaining the arch of the foot. The Flexor digitorum longus and Flexor hallucis longus are the direct flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking, or in standing on tiptoe. In consequence of the oblique direction of its tendons the Flexor digitorum longus would draw the toes medialward, were it not for the Quadratus plantae, which is inserted into the lateral side of the tendon, and draws it to the middle line of the foot. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly upon the talus.

3. The Lateral Crural Muscles (Fig. 553).

Peroneus longus.

Peroneus brevis.

Dissection.—The muscles are readily exposed by removing the fascia covering their surface, from below upward, in the line of direction of their fibres.

The **Peroneus longus** is situated at the upper part of the lateral side of the leg, and is the more superficial of the two muscles. It *arises* from the head and

upper two-thirds of the lateral surface of the body of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the front and back of the leg; occasionally also by a few fibres from the lateral condyle of the tibia. Between its attachments to the head and to the body of the fibula there is a gap through which the common peroneal nerve passes to the front of the leg. It ends in a long tendon, which runs behind the lateral malleolus, in a groove common to it and the tendon of the *Peroneus brevis*, behind which it lies; the groove is converted into a canal by the superior peroneal retinaculum, and the tendons in it are contained in a common mucous sheath. The tendon then extends obliquely forward across the lateral side of the calcaneus, below the trochlear process, and the tendon of the *Peroneus brevis*, and under cover of the inferior peroneal retinaculum. It crosses the lateral side of the cuboid, and then runs on the under surface of that bone in a groove which is converted into a canal by the long plantar ligament; the tendon then crosses the sole of the foot obliquely, and is inserted into the lateral side of the base of the first metatarsal bone and the lateral side of the first cuneiform. Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points: first, behind the lateral malleolus; secondly, on the cuboid bone; in both of these situations the tendon is thickened, and, in the latter, a sesamoid fibrocartilage (sometimes a bone), is usually developed in its substance.

The *Peroneus brevis* lies under cover of the *Peroneus longus*, and is a shorter and smaller muscle. It *arises* from the lower two-thirds of the lateral surface of the body of the fibula; medial to the *Peroneus longus*; and from the intermuscular septa separating it from the adjacent muscles on the front and back of the leg. The fibres pass vertically downward, and end in a tendon which runs behind the lateral malleolus along with but in front of that of the preceding muscle, the two tendons being enclosed in the same compartment, and lubricated by a common mucous sheath. It then runs forward on the lateral side of the calcaneus, above the trochlear process and the tendon of the *Peroneus longus*, and is *inserted* into the tuberosity at the base of the fifth metatarsal bone, on its lateral side.

On the lateral surface of the calcaneus the tendons of the *Peronei longus* and *brevis* occupy separate osseoponeurotic canals formed by the calcaneus and the perineal retinacula; each tendon is enveloped by a forward prolongation of the common mucous sheath.

Nerves.—The *Peronei longus* and *brevis* are supplied by the fourth and fifth lumbar and first sacral nerves through the superficial peroneal nerve.

Actions.—The *Peronei longus* and *brevis* extend the foot upon the leg, in conjunction with the *Tibialis posterior*, antagonizing the *Tibialis anterior* and *Peroneus tertius*, which are flexors of the foot. The *Peroneus longus* also everts the sole of the foot, and from the oblique direction of the tendon across the sole of the foot is an important agent in the maintenance of the transverse arch. Taking their fixed points below, the *Peronei* serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the tendency of the superincumbent weight is to throw the leg medialward; the *Peroneus longus* overcomes this tendency by drawing on the lateral side of the leg.

Applied Anatomy.—The student should now consider the positions of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding bloodvessels, and especially their actions upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as *club-foot*. The most simple and common deformity, and one that is rarely, if ever, congenital, is *talipes equinus*, the heel being raised by the rigidity and contraction of the *Gastrocnemius* so that the patient walks upon the ball of the foot. In *talipes varus* the foot is forcibly adducted and the medial side of the sole raised, sometimes to a right angle with the ground, by the action of the *Tibiales anterior* and *posterior*. In *talipes valgus* the lateral edge of the foot is raised by the *Peronei*, and the patient walks on the medial side of the foot. In *talipes calcaneus* the toes are raised by the *Extensor* muscles, the heel is depressed and the patient walks upon it. Other varieties of deformity are met with, as *talipes equinovarus*, *equinovalgus*, and *calcaneovalgus*, whose names sufficiently indicate their nature. Of these, *talipes equinovarus* is the most common congenital form; the heel is raised by the tendo calcaneus, the medial border of the foot drawn upward by the *Tibialis anterior*, the anterior two-thirds twisted medialward

by the Tibialis posterior, and the arch increased by the contraction of the plantar aponeurosis, so that the patient walks on the middle of the lateral border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia; by this means the foot regains its proper position, and the tendons heal by the organization of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it.

Rupture of a few of the fibres of the Gastrocnemius, or rupture of the Plantaris tendon, not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn tennis, and is hence known as *lawn-tennis leg*. The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo calcaneus is also sometimes ruptured. It is stated that John Hunter ruptured his tendo calcaneus while dancing, at the age of forty. The bursa between the tendo calcaneus and the posterior surface of the calcaneus sometimes becomes inflamed, especially in pedestrians and "long-distance" walkers. It causes great and disabling pain, and entirely prevents the sufferer from continuing his walk.

THE FASCIA AROUND THE ANKLE.

Fibrous bands, or thickened portions of the fascia, bind down the tendons in front of and behind the ankle in their passage to the foot. They comprise three ligaments, viz., the transverse crural, the cruciate crural, and the laciniate; and the superior and inferior peroneal retinacula.

Ten.

Peronaeus brevis *Peronaeus tertius*

FIG. 554.—The mucous sheaths of the tendons around the ankle. Lateral aspect.

Transverse Crural Ligament (*ligamentum transversum cruris*; upper part of *anterior annular ligament*) (Fig. 554).—The transverse crural ligament binds down the tendons of Extensor digitorum longus, Extensor hallucis longus, Peronaeus tertius, and Tibialis anterior as they descend on the front of the tibia and fibula; under it are found also the anterior tibial vessels and deep peroneal nerve. It is attached laterally to the lower end of the fibula, and medially to the tibia; above it is continuous with the fascia of the leg.

Cruciate Crural Ligament (*ligamentum cruciatum cruris*; lower part of *anterior annular ligament*) (Figs. 554, 555).—The cruciate crural ligament is a Y-shaped band placed in front of the ankle-joint, the stem of the Y being attached laterally

to the upper surface of the calcaneus, in front of the depression for the interosseous talocalcaneal ligament; it is directed medialward as a double layer, one lamina passing in front of, and the other behind, the tendons of the Peroneus tertius and Extensor digitorum longus. At the medial border of the latter tendon these two layers join together, forming a compartment in which the tendons are enclosed. From the medial extremity of this sheath the two limbs of the Y diverge: one is directed upward and medialward, to be attached to the tibial malleolus, passing over the Extensor hallucis longus and the vessels and nerves, but enclosing the Tibialis anterior by a splitting of its fibres. The other limb extends downward and medialward, to be attached to the border of the plantar aponeurosis, and passes over the tendons of the Extensor hallucis longus and Tibialis anterior and also the vessels and nerves.

Tendocalcaneus

FIG. 555.—The mucous sheaths of the tendons around the ankle. Medial aspect.

Laciniate Ligament (*ligamentum lacinatum*; *internal annular ligament*).—The laciniate ligament is a strong fibrous band, extending from the tibial malleolus above to the margin of the calcaneus below, converting a series of bony grooves in this situation into canals for the passage of the tendons of the Flexor muscles and the posterior tibial vessels and tibial nerve into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar aponeurosis and the fibres of origin of the Abductor hallucis muscle. Enumerated from the medial side, the four canals which it forms transmit the tendon of the Tibialis posterior; the tendon of the Flexor digitorum longus; the posterior tibial vessels and tibial nerve, which run through a broad space beneath the ligament; and lastly, in a canal formed partly by the talus, the tendon of the Flexor hallucis longus.

Peroneal Retinacula.—The peroneal retinacula are fibrous bands which bind down the tendons of the Peronei longus and brevis as they run across the lateral side of the ankle. The fibres of the **superior retinaculum** (*external annular ligament*) are attached *above* to the lateral malleolus and *below* to the lateral surface of the calcaneus. The fibres of the **inferior retinaculum** are continuous in *front* with those of the cruciate crural ligament; *behind* they are attached to the lateral surface of the calcaneus; some of the fibres are fixed to the peroneal trochlea, forming a septum between the tendons of the Peronei longus and brevis.

The **Flexor digitorum brevis** lies in the middle of the sole of the foot, immediately above the central part of the plantar aponeurosis, with which it is firmly united. Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia. It *arises* by a narrow tendon, from the medial process of the tuberosity of the calcaneus, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and the adjacent muscles. It passes forward, and divides into four tendons, one for each of the four lesser toes. Opposite the bases of the first phalanges, each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor digitorum longus; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long Flexor tendon. Finally, it divides a second time, and is *inserted* into the sides of the second phalanx about its middle. The mode of division of the tendons of the Flexor digitorum brevis, and of their insertion into the phalanges, is analogous to that of the tendons of the Flexor digitorum sublimis in the hand.

Fibrous Sheaths of the Flexor Tendons.—The terminal portions of the tendons of the long and short Flexor muscles are contained in osseaponeurotic canals similar in their arrangement to those in the fingers. These canals are formed above by the phalanges and below by fibrous bands, which arch across the tendons, and are attached on either side to the margins of the phalanges. Opposite the bodies of the proximal and second phalanges the fibrous bands are strong, and the fibres are transverse; but opposite the joints they are much thinner, and the fibres are directed obliquely. Each canal contains a mucous sheath, which is reflected on the contained tendons.

The Abductor digiti quinti (*Abductor minimi digiti*) lies along the lateral border of the foot, and is in relation by its medial margin with the lateral plantar vessels and nerves. It *arises*, by a broad origin, from the lateral process of the tuberosity of the calcaneus, from the under surface of the calcaneus between the two processes of the tuberosity, from the forepart of the medial process, from the plantar aponeurosis, and from the intermuscular septum

FIG. 556.—Muscles of the sole of the foot.
First layer

between it and the Flexor digitorum brevis. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is *inserted*, with the Flexor digiti quinti brevis, into the fibular side of the base of the first phalanx of the fifth toe.

Dissection.—The muscles of the superficial layer should be divided at their origin by inserting the knife beneath each, and cutting obliquely backward, so as to detach them from the bone; they should then be drawn forward, in order to expose the second layer, but not cut away at their insertion. The two layers are separated by a thin membrane, the *deep plantar aponeurosis*, on the removal of which is seen the tendon of the Flexor digitorum longus, the Quadratus plantae,

the tendon of the Flexor hallucis longus, and the Lumbricales. The long Flexor tendons diverge from each other at an acute angle; the Flexor hallucis longus runs along the inner side of the foot, on a plane superior to that of the Flexor digitorum longus, the direction of the latter being obliquely outward.

The Second Layer (Fig. 557).

Quadratus plantae.

Lumbricales.

The **Quadratus plantae** (*Flexor accessorius*) is separated from the muscles of the first layer by the lateral plantar vessels and nerve. It *arises* by two heads, which are separated from each other by the long plantar ligament: the **medial** or **larger head** is muscular, and is attached to the medial concave surface of the calcaneus, below the groove which lodges the tendon of the Flexor hallucis longus; the **lateral head**, flat and tendinous, *arises* from the lateral border of the inferior surface of the calcaneus, in front of the lateral process of its tuberosity, and from the long plantar ligament. The two portions join at an acute angle, and end in a flattened band which is *inserted* into the lateral margin and upper and under surfaces of the tendon of the Flexor digitorum longus, forming a kind of groove, in which the tendon is lodged. It usually sends slips to those tendons of the Flexor digitorum longus which pass to the second, third, and fourth toes.

The **Lumbricales** are four small muscles, accessory to the tendons of the Flexor digitorum longus and numbered from the medial side of the foot; they *arise* from these tendons, as far back as their angles of division, each springing from two tendons, except the first. The muscles end in tendons, which pass forward on the medial sides of the four lesser toes, and are *inserted* into the expansions of the tendons of the Extensor digitorum longus on the dorsal surfaces of the first phalanges.

Dissection.—The Flexor tendons should be divided at the back part of the foot, and the Quadratus plantae at its origin, and drawn forward, in order to expose the third layer.

The Third Layer (Fig. 558).

Flexor hallucis brevis.

Adductor hallucis.

Flexor digiti quinti brevis.

The **Flexor hallucis brevis** *arises*, by a pointed tendinous process, from the medial part of the under surface of the cuboid bone, from the contiguous portion of the third cuneiform, and from the prolongation of the tendon of the Tibialis posterior which is attached to that bone. It divides in front into two portions, which are inserted into the medial and lateral sides of the base of the first phalanx of the great toe, a sesamoid bone being present in each tendon at its insertion. The **medial portion** is blended with the Abductor hallucis previous to its insertion; the **lateral portion** with the Adductor hallucis; the tendon of the Flexor hallucis longus lies in a groove between them; the lateral portion is sometimes described as the **first Interosseous plantaris**.

The **Adductor hallucis** (*Adductor obliquus hallucis*) *arises* by two heads—oblique and transverse. The **oblique head** is a large, thick, fleshy mass, crossing the foot obliquely and occupying the hollow space under the first, second, third, and fourth metatarsal bones. It *arises* from the bases of the second, third, and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus, and is *inserted*, together with the lateral portion of the Flexor hallucis brevis, into the lateral side of the base of the first phalanx of the great toe. The **transverse head** (*Transversus pedis*) is a narrow, flat fasciculus which *arises* from the plantar metatarsophalangeal ligaments of the third, fourth, and fifth toes (sometimes only from the third and fourth), and from the transverse ligament of the metatarsus. It is *inserted* into the lateral side of the base of the first phalanx of the great toe, its fibres blending with the tendon of insertion of the oblique head.

The Abductor, Flexor brevis, and Adductor of the great toe, like the similar muscles of the thumb, give off, at their insertions, fibrous expansions to blend with the tendons of the Extensor digitorum longus.

FIG. 557 — Muscles of the sole of the foot.
Second layer

FIG. 558 — Muscles of the sole of the foot.
Third layer.

The **Flexor digiti quinti brevis** (*Flexor brevis minimi digiti*) lies under the metatarsal bone of the little toe, and resembles one of the Interossei. It arises from the base of the fifth metatarsal bone, and from the sheath of the Peronæus longus; its tendon is inserted into the lateral side of the base of the first phalanx of the fifth toe. Occasionally a few of the deeper fibres are inserted into the lateral part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the **Opponens digiti quinti**.

The Fourth Layer.

Interossei.

The **Interossei** in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the *second* digit, instead of that

of the *third*. They are seven in number, and consist of two groups, dorsal and plantar.

The **Interossei dorsales** (*Dorsal interossei*) (Fig. 559), *four* in number, are situated between the metatarsal bones. They are bipenniform muscles, each *arising* by two heads from the adjacent sides of the metatarsal bones between which it is placed; their tendons are *inserted* into the bases of the first phalanges, and into the aponeurosis of the tendons of the Extensor digitorum longus. In the angular interval left between the heads of each of the three lateral muscles, one of the perforating arteries passes to the dorsum of the foot; through the space between the heads of the first muscle the deep plantar branch of the dorsalis pedis artery enters the sole of the foot. The first is *inserted* into the medial side of the second toe; the other three are *inserted* into the lateral sides of the second, third, and fourth toes.

FIG. 559.—The Interossei dorsales. Left foot.

FIG. 560.—The Interossei plantares. Left foot.

The **Interossei plantares** (*Plantar interossei*) (Fig. 560), *three* in number, lie beneath rather than between the metatarsal bones, and each is connected with but one metatarsal bone. They *arise* from the bases and medial sides of the bodies of the third, fourth, and fifth metatarsal bones, and are *inserted* into the medial sides of the bases of the first phalanges of the same toes, and into the aponeuroses of the tendons of the Extensor digitorum longus.

Nerves.—The Flexor digitorum brevis, the Flexor hallucis brevis, the Abductor hallucis, and the first Lumbricalis are supplied by the medial plantar nerve; all the other muscles in the sole of the foot by the lateral plantar. The first Interosseous dorsalis frequently receives an extra filament from the medial branch of the deep peroneal nerve on the dorsum of the foot, and the second Interosseous dorsalis a twig from the lateral branch of the same nerve.

Actions.—All the muscles of the foot act upon the toes, and may be grouped as abductors, adductors, flexors, or extensors. The *abductors* are the Interossei dorsales, the Abductor hallucis, and the Abductor digiti quinti. The Interossei dorsales are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe medialward, toward the great toe, the second muscle draws the same toe lateralward, and the third and fourth draw the third and fourth toes in the same direction. Like the Interossei in the hand, each assists in flexing the first phalanx and extending the second and third phalanges. The Abductor hallucis abducts the great toe from the second, and also flexes its proximal phalanx.

In the same way the action of the Abductor digiti quinti is twofold, as an abductor of this toe from the fourth, and also as a flexor of its proximal phalanx. The *adductors* are the Interossei plantares and the Adductor hallucis. The Interossei plantares adduct the third, fourth, and fifth toes toward the imaginary line passing through the second toe, and by means of their insertions into the aponeuroses of the Extensor tendons they assist in flexing the proximal phalanges and extending the middle and terminal phalanges. The oblique head of the Adductor hallucis is chiefly concerned in adducting the great toe toward the second one, but also assists in flexing this toe; the transverse head approximates all the toes and thus increases the curve of the transverse arch of the metatarsus. The *flexors* are the Flexor digitorum brevis, the Quadratus plantae, the Flexor hallucis brevis, the Flexor digiti quinti brevis, and the Lumbricales. The Flexor digitorum brevis flexes the second phalanges upon the first, and, continuing its action, flexes the first phalanges also, and brings the toes together. The Quadratus plantae assists the Flexor digitorum longus and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor digiti quinti brevis flexes the little toe and draws its metatarsal bone downward and medialward. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanges, and by their insertions into the tendons of the Extensor digitorum longus aid that muscle in straightening the middle and terminal phalanges. The Extensor digitorum brevis extends the first phalanx of the great toe and assists the long Extensor in extending the next three toes, and at the same time gives to the toes a lateral direction when they are extended.

femur

FIG. 561.—Fracture of the neck of the femur within the articular capsule.

Applied Anatomy.—The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fracture are selected for illustration and description.

In fracture of the neck of the femur inside the articular capsule (Fig. 561), the characteristic signs are slight shortening of the limb, and eversion of the foot, neither of which may appear until some time after the injury. The eversion is caused by the weight of the limb rotating it outward. The shortening is produced by the contractions of all the muscles about the joint.

In fracture of the femur just below the trochanters (Fig. 562), the upper fragment is tilted forward almost at right angles with the pelvis, by the Psoas major and Iliacus; and, at the same time, everted and drawn laterally by the external rotator muscles and Glutei, causing a marked prominence at the upper and lateral side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, because the lower fragment is drawn upward by the Rectus femoris in front, and the Biceps femoris, Semimembranosus, and Semitendinosus behind; it is, at the same time, everted. This fracture may be reduced by relaxation of all the muscles involved, to effect which the limb should be put up with the thigh flexed on the pelvis and the leg on the thigh.

Oblique fracture of the femur *immediately above the condyles* (Fig. 563) is a formidable injury, and attended with considerable displacement. On examination of the limb, the lower fragment may be felt deep in the popliteal fossa, being drawn backward by the Gastrocnemius, and upward by the Hamstrings and Rectus femoris. The pointed end of the upper fragment is drawn medialward by the Pectineus and Adductores, and tilted forward by the Psoas major and Iliacus, piercing the Rectus, and occasionally the integument. Relaxation of these muscles, and direct approximation of the broken fragments, are effected by traction with the limb fully flexed. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed, the Rectus femoris being held down by the fractured end of the bone.

FIG

FIG. 562.—Fracture of the femur below the trochanters.

FIG. 563.—Fracture of the femur above the condyles.

In transverse fracture of the *patella* (Fig. 564) the fragments are separated by the action of the Quadriceps femoris and by the effusion which takes place into the joint; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone.

In oblique fracture of the *body of the tibia* (Fig. 565), if the fracture has taken place obliquely from above, downward and forward, the fragments ride over one another, the lower fragment being drawn backward and upward by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forward immediately beneath the integument, often protruding through it, and rendering the fracture compound. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forward, rising up on the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is sometimes necessary, however, in compound fracture to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

Fracture of the *fibula with dislocation of the foot lateralward*, commonly known as *Pott's fracture*, is one of the most frequent injuries in the region of the ankle-joint. The fibula is fractured about 7 or 8 cm. above the ankle; in addition to this the medial malleolus is broken off, or the deltoid ligament torn through, and the talus displaced from the corresponding surface of the tibia. The

foot is markedly everted, and the sharp edge of the upper end of the fractured malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury can generally be reduced by flexing the leg at right angles with the thigh, which relaxes

FIG. 564.—Fracture of the patella.

FIG. 565.—Oblique fracture of the body of the tibia.

all the opposing muscles, and by making extension from the ankle and counter-extension at the knee. There is later a great tendency for the foot to fall backward at the ankle-joint, and constant supervision is required to counteract this.

ANGIOLOGY.

THE vascular system is divided for descriptive purposes into (a) the **blood vascular system**, which comprises the heart and bloodvessels for the circulation of the blood; and (b) the **lymph vascular system**, consisting of lymph glands and lymphatic vessels, through which a colorless fluid, the **lymph**, circulates. It must be noted, however, that the two systems communicate with each other and are intimately associated developmentally.

The heart is the central organ of the blood vascular system, and consists of a hollow muscle; by its contraction the blood is pumped to all parts of the body through a complicated series of tubes, termed **arteries**. The arteries undergo enormous ramification in their course throughout the body, and end in minute vessels, called **arterioles**, which in their turn open into a close-meshed network of microscopic vessels, termed **capillaries**. After the blood has passed through the capillaries it is collected into a series of larger vessels, called **veins**, by which it is returned to the heart. The passage of the blood through the heart and bloodvessels constitutes what is termed the **circulation of the blood**, of which the following is an outline.¹

The human heart is divided by septa into right and left halves, and each half is further divided into two cavities, an upper termed the **atrium** and a lower the **ventricle**. The heart therefore consists of four chambers, two, the right atrium and right ventricle, forming the right half, and two, the left atrium and left ventricle the left half. The right half of the heart contains venous or impure blood; the left, arterial or pure blood. The atria are receiving chambers, and the ventricles distributing ones. From the cavity of the left ventricle the pure blood is carried into a large artery, the **aorta**, through the numerous branches of which it is distributed to all parts of the body, with the exception of the lungs. In its passage through the capillaries of the body the blood gives up to the tissues the materials necessary for their growth and nourishment, and at the same time receives from the tissues the waste products resulting from their metabolism. In doing so it is changed from arterial into venous blood, which is collected by the veins and through them returned to the right atrium of the heart. From this cavity the impure blood passes into the right ventricle, and is thence conveyed through the **pulmonary arteries** to the lungs. In the capillaries of the lungs it again becomes arterialized, and is then carried to the left atrium by the **pulmonary veins**. From the left atrium it passes into the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or **systemic circulation**, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or **pulmonary circulation**.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is conveyed by the **portal vein** to the liver. In the liver this vein divides, like an artery, and ultimately ends in capillary-like vessels (*sinusoids*), from which the rootlets of a series of veins, called the **hepatic veins**, arise; these carry the blood into the inferior vena cava,

¹ The composition of the blood is described on pp. 61 to 64.

whence it is conveyed to the right atrium. From this it will be seen that the blood contained in the portal vein passes through two sets of vessels: (1) the capillaries in the spleen, pancreas, stomach, etc., and (2) the sinusoids in the liver.

Speaking generally, the arteries may be said to contain pure and the veins impure blood. This is true of the systemic, but not of the pulmonary vessels, since it has been seen that the impure blood is conveyed from the heart to the lungs by the pulmonary arteries, and the pure blood returned from the lungs to the heart by the pulmonary veins. Arteries, therefore, must be defined as vessels which convey blood from the heart, and veins as vessels which return blood to the heart.

Structure of Arteries (Fig. 566).—The arteries are composed of three coats: an internal or endothelial coat (*tunica intima* of Kölliker); a middle or muscular coat (*tunica media*); and an external or connective-tissue coat (*tunica adventitia*). The two inner coats together are very easily separated from the external, as by the ordinary operation of tying a ligature around an artery. If a fine string be tied forcibly upon an artery and then taken off, the external coat will be found undivided, but the two inner coats are divided in the track of the ligature and can easily be further dissected from the outer coat.

The inner coat (*tunica intima*) can be separated from the middle by a little maceration, or it may be stripped off in small pieces; but, on account of its friability, it cannot be separated as a complete membrane. It is a fine, transparent, colorless structure which is highly elastic, and, after death, is commonly corrugated into longitudinal wrinkles. The inner coat consists of: (1) A layer of pavement endothelium, the cells of which are polygonal, oval, or fusiform, and have very distinct round or oval nuclei. This endothelium is brought into view most distinctly by staining with nitrate of silver. (2) A subendothelial layer, consisting of delicate connective tissue with branched cells lying in the interspaces of the tissue; in arteries of less than 2 mm. in diameter the sub-endothelial layer consists of a single stratum of stellate cells, and the connective tissue is only largely developed in vessels of a considerable size. (3) An elastic or fenestrated layer, which consists of a membrane containing a net-work of elastic fibres, having principally a longitudinal direction, and in which, under the microscope, small elongated apertures or perforations may be seen, giving it a fenestrated appearance. It was therefore called by Henle the **fenestrated membrane**. This membrane forms the chief thickness of the inner coat, and can be separated into several layers, some of which present the appearance of a net-work of longitudinal elastic fibres, and others a more membranous character, marked by pale lines having a longitudinal direction. In minute arteries

FIG. 566.—Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. X 350. (Klein and Noble Smith.) A Artery, showing the nucleated endothelium, *e*, which lines it; the vessel being contracted, the endothelial cells appear very thick. Underneath the endothelium is the wavy elastic lamina. The chief part of the wall of the vessel is occupied by the circular muscle coat *m*; the rod-shaped nuclei of the muscle cells are well seen. Outside this is *a*, part of the adventitia. This is composed of bundles of connective tissue fibres, shown in section, with the nuclei of the connective tissue corpuscles. The adventitia gradually merges into the surrounding connective tissue. V. Vein showing a thin endothelial membrane, *e*, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media *m*. This latter is composed of a few circular unstriated muscle cells *c*. The adventitia, similar in structure to that of an artery.

the fenestrated membrane is a very thin layer; but in the larger arteries, and especially in the aorta, it has a very considerable thickness.

The **middle coat** (*tunica media*) is distinguished from the inner by its color and by the transverse arrangement of its fibres. In the smaller arteries it consists principally of plain muscle fibres in fine bundles, arranged in lamellæ and disposed circularly around the vessel. These lamellæ vary in number according to the size of the vessel; the smallest arteries having only a single layer (Fig. 567), and those slightly larger three or four layers. It is to this coat that the thickness of the wall of the artery is mainly due (Fig. 566A, *m*). In the larger arteries, as the iliac, femoral, and carotid, elastic fibres unite to form lamellæ which alternate with the layers of muscular fibres; these lamellæ are united to one another by elastic fibres which pass between the muscular bundles, and are connected with the fenestrated membrane of the inner coat (Fig. 568). In the largest arteries, as the aorta and innominate, the amount of elastic tissue is very considerable; in these vessels a few bundles of white connective tissue also have been found in

the middle coat. The muscle fibre cells are about 50μ in length and contain well-marked, rod-shaped nuclei, which are often slightly curved.

The **external coat** (*tunica adventitia*) consists mainly of fine and closely felted bundles of white connective tissue, but also contains elastic fibres in all but the smallest arteries. The elastic tissue is much more abundant next the tunica media, and it is sometimes described as forming here, between the adventitia and media, a special layer, the **tunica elastica externa** of Henle. This layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin; but in small arteries it is of greater proportionate thickness. In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; while in the smallest arteries, just above the capillaries, the elastic fibres are wanting, and the connective tissue of which the coat is composed becomes more nearly homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope, which finally disappears.

Some arteries have extremely thin walls in proportion to their size; this is especially the case in those situated in the cavity of the cranium and vertebral canal, the difference depending on the thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are included in thin fibro-areolar investments, which form their **sheaths**. The vessel is loosely connected with its sheath by delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are not included in sheaths.

All the larger arteries, like the other organs of the body, are supplied with bloodvessels. These

nutrient vessels, called the **vasa vasorum**, arise from a branch of the artery, or from a neighboring vessel, at some considerable distance from the point at which they are distributed; they

ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat, but do not, in man, penetrate the other coats; in some of the larger mammals a few vessels have been traced into the middle coat. Minute veins return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymphatic vessels are also present in the outer coat.

Arteries are also supplied with nerves, which are derived from the sympathetic, but may pass through the cerebrospinal nerves. They form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller arteries as single filaments, or bundles of filaments which twist around the vessel and unite with each other in a plexiform manner. The branches derived from these plexuses penetrate the external coat and are distributed principally to the muscular tissue of the middle coat, and thus regulate, by causing the contraction and relaxation of this tissue the amount of blood sent to any part.

The Capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the splenic pulp, and of the placenta) terminate in net-works of vessels which pervade nearly every tissue of the body. These vessels, from their minute size, are termed capillaries. They are interposed between the smallest branches of the arteries and the commencing veins, constituting a net-work, the branches of which maintain the same diameter throughout; the meshes of the net-work are more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The *diameters* of the capillaries vary in the different tissues of the body, the usual size being about 8μ . The smallest are those of the brain and the mucous membrane of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as 20μ in diameter. The *form* of the capillary net varies in the different tissues, the meshes being generally rounded or elongated.

The *rounded form of mesh* is most common, and prevails where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; the meshes are not of an absolutely circular outline, but more or less angular, sometimes nearly quadrangular, or polygonal, or more often irregular.

Elongated meshes are observed in the muscles and nerves, the meshes resembling parallelograms in form, the long axis of the mesh running parallel with the long axis of the nerve or muscle. Sometimes the capillaries have a *looped arrangement*; a single vessel projecting from the common net-work and returning after forming one or more loops, as in the papillæ of the tongue and skin.

The number of the capillaries and the size of the meshes determine the degree of vascularity of a part. The closest network and the smallest interspaces are found in the lungs and in the choroid coat of the eye. In these situations the interspaces are smaller than the capillary vessels themselves. In the intertubular plexus of the kidney, in the conjunctiva, and in the cutis, the interspaces are from three to four times as large as the capillaries which form them; and in the brain from eight to ten times as large as the capillaries in their long diameters, and from four to six times as large in their transverse diameters. In the adventitia of arteries the width of the meshes is ten times that of the capillary vessels. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood; the meshes of the network are very narrow in all growing parts, in the glands, and in the mucous membranes, wider in bones and ligaments which are comparatively inactive; bloodvessels are nearly altogether absent in tendons, in which very little organic change occurs after their formation. In the liver the capillaries take a more or less radial course toward the intralobular vein, and their walls are incomplete, so that the blood comes into direct contact with the liver cells. These vessels in the liver are not true capillaries but "sinusoids;" they are developed by the growth of columns of liver cells into the blood spaces of the embryonic organ.

Structure.—The wall of a capillary consists of a fine transparent endothelial layer, composed of cells joined edge to edge by an interstitial cement substance, and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver the edges which bound the epithelial cells are brought into view (Fig. 569). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be displayed by carmine or hematoxylin. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. They have been believed to be the situations through which the colorless corpuscles of the blood, when migrating from the bloodvessels, emerge; but this view, though probable, is not universally accepted.

Kolossow describes these cells as having a rather more complex structure. He states that each consists of two parts: of hyaline ground plates, and of a protoplasmic granular part, in which is imbedded the nucleus, on the outside of the ground plates. The hyaline internal coat of the capillaries does not form a complete membrane, but consists of "plates" which are inelastic, and though in contact with each other are not continuous; when therefore the capillaries are subjected to intravascular pressure, the plates become separated from each other; the protoplasmic portions of the cells, on the other hand, are united together. In some organs, *e. g.*, the glomeruli

of the kidneys, intercellular cement cannot be demonstrated in the capillary wall and the cells are believed to form a syncytium.

In many situations a delicate sheath or envelope of branched nucleated connective tissue cells is found around the simple capillary tube, particularly in the larger ones; and in other places, especially in the glands, the capillaries are invested with retiform connective tissue.

Sinusoids.—In certain organs, viz., the heart, the liver, the suprarenal and parathyroid glands, the glomus caroticum and glomus coccygeum, the smallest bloodvessels present various differences from true capillaries. They are wider, with an irregular lumen, and have no connective tissue covering, their endothelial cells being in direct contact with the cells of the organ. Moreover, they are either arterial or venous and not intermediate as are the true capillaries. These vessels have been called *sinusoids* by Minot. They are formed by columns of cells or trabeculae pushing their way into a large bloodvessel or blood space and carrying its endothelium before them; at the same time the wall of the vessel or space grows out between the cell columns.

Structure of Veins.—The veins, like the arteries, are composed of three coats: internal, middle, and external; and these coats are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective tissue or areolar (Fig. 570). The main difference between the veins and the arteries is in the comparative weakness of the middle coat in the former.

In the smallest veins the three coats are hardly to be distinguished (Fig. 567). The endothelium is supported on a membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (*adventitia*), while the inner is composed of a network of longitudinal elastic fibres (*media*). In the veins next above these in size (0.4 mm. in diameter), according to Kölliker, a connective tissue layer containing numerous muscle fibres circularly disposed can be traced, forming the middle coat, while the elastic and connective tissue elements of the outer coat become more distinctly perceptible. In the middle-sized veins the typical structure of these vessels becomes clear. The endothelium is of the same character as in the arteries, but its cells are more oval and less fusiform. It is supported by a connective tissue layer, consisting of a delicate net-work of branched cells, and external to this is a layer of elastic fibres disposed in the form of a net-work in place of the definite fenestrated membrane seen in the arteries. This constitutes the **internal coat**. The **middle coat** is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a transverse layer of muscular tissue. The white fibrous element is in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The **outer coat** consists, as in the arteries, of areolar tissue, with longitudinal elastic fibres. In the largest veins the outer coat is from two to five times thicker than the middle coat, and contains a large number of longitudinal muscular fibres. These are most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the portal vein, and in the external iliac, renal, and azygos veins. In the renal and portal veins they extend through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. All the large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting: (1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater of the brain and medulla spinalis; (3) in the veins of the retina; (4) in the veins of the cancellous tissue of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an internal endothelial lining supported on one or more layers of areolar tissue.

Most veins are provided with valves which serve to prevent the reflux of the blood. Each valve is formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and is covered on both surfaces with endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and some-

FIG. 569.—Capillaries from the mesentery of a guinea-pig, after treatment with solution of nitrate of silver. a. Cells. b. Their nuclei.

times only one. The valves are semilunar. They are attached by their convex edges to the wall of the vein; the concave margins are free, directed in the course of the venous current, and lie in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. The wall of the vein on the cardiac side of the point of attachment of each valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially of the lower extremities, these vessels

having to conduct the blood against the force of gravity. They are absent in the very small veins, i. e., those less than 2 mm. in diameter, also in the vena cavae, hepatic, renal, uterine, and ovarian veins. A few valves are found in each spermatic vein, and one also at its point of junction with the renal vein or inferior vena cava respectively. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. A few valves are occasionally found in the azygos and intercostal veins. Rudimentary valves are found in the tributaries of the portal venous system.

The veins, like the arteries, are supplied with nutrient vessels, *VASA VASORUM*. Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

THE THORACIC CAVITY.

The heart and lungs are situated in the thorax, the walls of which afford them protection. The heart lies between the two lungs, and is enclosed within a fibrous bag, the *pericardium*, while each lung is invested by a serous membrane, the *pleura*. The skeleton of the thorax, and the shape and boundaries of the cavity, have already been described (page 216).

The Cavity of the Thorax.—The capacity of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity

extends above the anterior parts of the first ribs into the neck. The size of the thoracic cavity is constantly varying during life with the movements of the ribs and Diaphragma, and with the degree of distention of the abdominal viscera. From the collapsed state of the lungs as seen when the thorax is opened in the dead body, it would appear as if the viscera only partly filled the cavity, but during life there is no vacant space, that which is seen after death being filled up by the expanded lungs.

The Upper Opening of the Thorax.—The parts which pass through the upper opening of the thorax are, from before backward, in or near the middle line, the Sternohyoideus and Sternothyreoideus muscles, the remains of the thymus, the inferior thyroid veins, the trachea, œsophagus, thoracic duct, and the Longus colli muscles; at the sides, the innominate artery, the left common carotid, left subclavian and internal mammary arteries and the costocervical trunks, the innominate veins, the vagus, cardiac, phrenic, and sympathetic nerves, the greater parts of the anterior divisions of the first thoracic nerves, and the recurrent nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the level of the sternal end of the first rib.

The Lower Opening of the Thorax.—The lower opening of the thorax is wider transversely than from before backward. It slopes obliquely downward and backward, so that the thoracic cavity is much deeper behind than in front. The Diaphragma (see page 493) closes the opening and forms the floor of the thorax. The floor is flatter at the centre than at the sides, and higher on the right side than on the left; in the dead body the right side reaches the level of the upper border of the fifth costal cartilage, while the left extends only to the corresponding part of the sixth costal cartilage. From the highest point on each side the floor slopes suddenly downward to the costal and vertebral attachments of the Diaphragma; this slope is more marked behind than in front, so that only a narrow space is left between the Diaphragma and the posterior wall of the thorax.

THE PERICARDIUM.

The **pericardium** (Fig. 571) is a conical fibro-serous sac, in which the heart and the roots of the great vessels are contained. It is placed behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the mediastinal cavity.

In front, it is separated from the anterior wall of the thorax, in the greater part of its extent, by the lungs and pleuræ; but a small area, somewhat variable in size, and usually corresponding with the left half of the lower portion of the body of the sternum and the medial ends of the cartilages of the fourth and fifth ribs of the left side, comes into direct relationship with the chest wall. The lower extremity of the thymus, in the child, is in contact with the front of the upper part of the pericardium. **Behind**, it rests upon the bronchi, the œsophagus, the descending thoracic aorta, and the posterior part of the mediastinal surface of each lung. **Laterally**, it is covered by the pleuræ, and is in relation with the mediastinal surfaces of the lungs; the phrenic nerve, with its accompanying vessels, descends between the pericardium and pleura on either side.

Structure of the Pericardium.—Although the pericardium is usually described as a single sac, an examination of its structure shows that it consists essentially of two sacs intimately connected with one another, but totally different in structure. The outer sac, known as the **fibrous pericardium**, consists of fibrous tissue. The inner sac, or **serous pericardium**, is a delicate membrane which lies within the fibrous sac and lines its walls; it is composed of a single layer of flattened cells resting on loose connective tissue. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being a potential one, except in front, where a small interspace exists below the apex of the heart.

The **fibrous pericardium** forms a flask-shaped bag, the neck of which is closed by its fusion with the external coats of the great vessels, while its base is attached to the central tendon and to the muscular fibres of the left side of the Diaphragm. In some of the lower mammals the base is either completely separated from the Diaphragm or joined to it by some loose areolar tissue; in man much of its diaphragmatic attachment consists of loose fibrous tissue which can be readily broken down, but over a small area the central tendon of the Diaphragm and the pericardium are completely fused. Above, the fibrous pericardium not only blends with the external coats of the great vessels, but is continuous with the pretracheal layer of the deep cervical fascia. By means of these upper and lower connections it is securely anchored within the thoracic cavity. It is also attached to the posterior surface of the sternum by the **superior and inferior sternopericardiac ligaments**; the upper passing to the manubrium, and the lower to the xiphoid process. On either side of the ascending aorta it sends upward a diverticulum; that on the left

FIG. 571.—Posterior wall of the pericardial sac, showing the lines of reflection of the serous pericardium on the great vessels.

side, somewhat conical in shape, passes between the arch of the aorta and the pulmonary artery, toward the ligamentum arteriosum, where it ends in a cecal extremity which is attached by loose connective tissue to the ligament; that on the right side passes between the ascending aorta and superior vena cava, and also ends in a blind extremity.

The vessels receiving fibrous prolongations from this membrane are: the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. The inferior vena cava enters the pericardium through the central tendon of the Diaphragm, and receives no covering from the fibrous layer.

The **serous pericardium** is, as already stated, a closed sac which lines the fibrous pericardium and is invaginated by the heart; it therefore consists of a **visceral** and a **parietal portion**. The visceral portion, or **epicardium**, covers the heart and the great vessels, and from the latter is continuous with the parietal layer which lines the fibrous pericardium. The portion which covers the vessels is arranged in the form of two tubes. The aorta and pulmonary artery are enclosed in one tube, the **arterial mesocardium**. The superior and inferior venæ cavæ and the four pulmonary veins are enclosed in a second tube, the **venous mesocardium**, the attachment of which to the parietal layer presents the shape of an inverted U. The *cul-de-sac* enclosed between the limbs of the \cap lies behind the left atrium and is known as the **oblique sinus**, while the passage between the venous and arterial mesocardia—i. e., between the aorta and pulmonary artery in front and the atria behind—is termed the **transverse sinus**.

The Ligament of the Left Vena Cava.—Between the left pulmonary artery and subjacent pulmonary vein is a triangular fold of the serous pericardium; it is known as the **ligament of the left vena cava** (*vestigial fold of Marshall*). It is formed by the duplicature of the serous layer over the remnant of the lower part of the left superior vena cava (*duct of Cuvier*), which becomes obliterated during fetal life, and remains as a fibrous band stretching from the highest left intercostal vein to the left atrium, where it is continuous with a small vein, the **vein of the left atrium** (*oblique vein of Marshall*), which opens into the coronary sinus.

The **arteries** of the pericardium are derived from the internal mammary and its musculophrenic branch, and from the descending thoracic aorta.

The **nerves** of the pericardium are derived from the vagus and phrenic nerves, and the sympathetic trunks.

Applied Anatomy.—Effusion of fluid into the pericardial sac often occurs in acute rheumatism or pneumonia, or in patients with chronic vascular and renal disease, embarrassing the heart's action and giving rise to signs of cardiac distress, such as pallor, a rapid and feeble pulse, dyspnoea, and restlessness. On examination, the apical cardiac impulse is absent, or replaced by a more extensive indefinite and wavering pulsation; it may appear to be in the second, third, or fourth left space, and is then not an apex impulse, as Potain has stated, but due to the impact of some portion of the heart wall nearer its base. In children the precordial intercostal spaces may bulge outward. The most striking sign, however, is the great increase in all directions of the precordial dullness on percussion. This becomes pear-shaped, the stalk of the pear reaching up to about the left sternoclavicular articulation; the dullness also extends some distance to the right of the sternum, particularly in the fifth interspace (Rotch). The fluid collects mainly on either side of the heart, and below it, especially on the left side, where the Diaphragma can yield more readily to pressure than it can on the right. Ewart has drawn attention to the presence of a square patch of dullness over the base of the left lung behind, reaching up to the level of the ninth or tenth rib, and extending laterally as far as the inferior angle of the scapula; the underlying lung tissue gives the physical signs of compression or collapse.

Paracentesis of the pericardium is often required to relieve the urgent cardiac or respiratory distress in these cases, and should be performed without hesitation and before the patient is in *extremis*. It may also be required when the pericardium is filled with blood or pus, and as it is advisable to perform this operation without transfixing the pleura, the puncture should be made either in the fifth or sixth intercostal space on the left side and close to the sternum, so as to avoid wounding the internal mammary artery, which descends about 1.25 cm. from the sternal margin; or the needle may be entered at the left costoxiphoid angle and made to pass upward and backward behind the lower end of the body of the sternum into the pericardial sac. Curschmann,¹ however, argues that the heart itself necessarily lies almost in contact with the anterior wall of the thorax even in cases of the largest pericardial effusion, so that there is risk of piercing it if the puncture is made in the fourth or fifth left intercostal space within even so much as 5 to 8 cm. of the sternal margin. He therefore advises that in moderately large pericardial effusions the trocar should be inserted in the left mamillary line, or lateral to it if the effusion is very large, in the fifth or sixth interspace. In consequence of the uncertain and varying position of the anterior reflexion of the pleura, transfixion of the pleural sac cannot always be avoided. *Pericardiectomy* is required when the effusion is of a purulent nature. In this operation a portion of the fifth or sixth costal cartilage is excised. An incision is made along the left border of the sternum from the upper border of the fourth cartilage to the seventh. The fifth costal cartilage is now separated from the sternum by means of a gouge, great care being taken not to let the instrument slip and penetrate too deeply. The cartilage is then seized with lion forceps and raised, the tissues beneath it being peeled off, so as to avoid wounding the internal mammary artery or the pleura. The Transversus thoracis is now scratched through, with a director or the nail of the index finger, close to the sternum, and the pericardium felt for and opened, the finger guarding the pleura and left internal mammary artery.

¹ Therapie der Gegenwart, 1905.

THE HEART (COR).

The **heart** is a hollow muscular organ of a somewhat conical form; it lies between the lungs in the middle mediastinum and is enclosed in the pericardium (Fig. 572). It is placed obliquely in the chest behind the body of the sternum and adjoining parts of the rib cartilages, and projects farther into the left than into the right half of the thoracic cavity, so that about one-third of it is situated on the right and two-thirds on the left of the median plane.

Size.—The heart, in the adult, measures about 12 cm. in length, 8 to 9 cm. in breadth at the broadest part, and 6 cm. in thickness. Its weight, in the male, varies from 280 to 340 grams; in the female, from 230 to 280 grams. The heart continues to increase in weight and size up to an advanced period of life: this increase is more marked in men than in women.

m

FIG. 572.—Front view of heart and lungs.

Component Parts.—As has already been stated (page 595), the heart is subdivided by septa into right and left halves, and a constriction subdivides each half of the organ into two cavities, the upper cavity being called the **atrium**, the lower the **ventricle**. The heart therefore consists of four chambers, viz., right and left atria, and right and left ventricles.

The division of the heart into four cavities is indicated on its surface by grooves. The atria are separated from the ventricles by the **coronary sulcus** (*auriculo-ventricular groove*); this contains the trunks of the nutrient vessels of the heart, and is deficient in front, where it is crossed by the root of the pulmonary artery. The **interatrial groove**, separating the two atria, is scarcely marked on the posterior

surface, while anteriorly it is hidden by the pulmonary artery and aorta. The ventricles are separated by two grooves, one of which, the **anterior longitudinal sulcus**, is situated on the sternocostal surface of the heart, close to its left margin, the other **posterior longitudinal sulcus**, on the diaphragmatic surface near the right margin; these grooves extend from the base of the ventricular portion to a notch, the **incisura apicis cordis**, on the acute margin of the heart just to the right of the apex.

The **base** (*basis cordis*) (Fig. 573), directed upward, backward, and to the right, is separated from the fifth, sixth, seventh, and eighth thoracic vertebræ by the œsophagus, aorta, and thoracic duct. It is formed mainly by the left atrium, and, to a small extent, by the back part of the right atrium. Somewhat quadrilateral in form, it is in relation above with the bifurcation of the pulmonary artery,

Azygos vein

FIG. 573. —Base and diaphragmatic surface of heart

and is bounded below by the posterior part of the coronary sulcus, containing the coronary sinus. On the right it is limited by the sulcus terminalis of the right atrium, and on the left by the ligament of the left vena cava and the oblique vein of the left atrium. The four pulmonary veins, two on either side, open into the left atrium, while the superior vena cava opens into the upper, and the anterior vena cava into the lower, part of the right atrium.

The Apex (*apex cordis*).—The apex is directed downward, forward, and to the left, and is overlapped by the left lung and pleura: it lies behind the fifth left intercostal space, 8 to 9 cm. from the mid-sternal line, or about 4 cm. below and 2 mm. to the medial side of the left mammary papilla.

The **sternocostal surface** (Fig. 574) is directed forward, upward, and to the left. Its lower part is convex, formed chiefly by the right ventricle, and traversed near its left margin by the anterior longitudinal sulcus. Its upper part is separated from

The **heart** is a hollow muscular organ of a somewhat conical form; it lies between the lungs in the middle mediastinum and is enclosed in the pericardium (Fig. 572). It is placed obliquely in the chest behind the body of the sternum and adjoining parts of the rib cartilages, and projects farther into the left than into the right half of the thoracic cavity, so that about one-third of it is situated on the right and two-thirds on the left of the median plane.

Size.—The heart, in the adult, measures about 12 cm. in length, 8 to 9 cm. in breadth at the broadest part, and 6 cm. in thickness. Its weight, in the male, varies from 280 to 340 grams; in the female, from 230 to 280 grams. The heart continues to increase in weight and size up to an advanced period of life: this increase is more marked in men than in women.

m

FIG. 572.—Front view of heart and lungs.

Component Parts.—As has already been stated (page 595), the heart is subdivided by septa into right and left halves, and a constriction subdivides each half of the organ into two cavities, the upper cavity being called the **atrium**, the lower the **ventricle**. The heart therefore consists of four chambers, viz., right and left atria, and right and left ventricles.

The division of the heart into four cavities is indicated on its surface by grooves. The atria are separated from the ventricles by the **coronary sulcus** (*auriculo-ventricular groove*); this contains the trunks of the nutrient vessels of the heart, and is deficient in front, where it is crossed by the root of the pulmonary artery. The **interatrial groove**, separating the two atria, is scarcely marked on the posterior

surface, while anteriorly it is hidden by the pulmonary artery and aorta. The ventricles are separated by two grooves, one of which, the **anterior longitudinal sulcus**, is situated on the sternocostal surface of the heart, close to its left margin, the other **posterior longitudinal sulcus**, on the diaphragmatic surface near the right margin; these grooves extend from the base of the ventricular portion to a notch, the **incisura apicis cordis**, on the acute margin of the heart just to the right of the apex.

The **base** (*basis cordis*) (Fig. 573), directed upward, backward, and to the right, is separated from the fifth, sixth, seventh, and eighth thoracic vertebræ by the œsophagus, aorta, and thoracic duct. It is formed mainly by the left atrium, and, to a small extent, by the back part of the right atrium. Somewhat quadrilateral in form, it is in relation above with the bifurcation of the pulmonary artery,

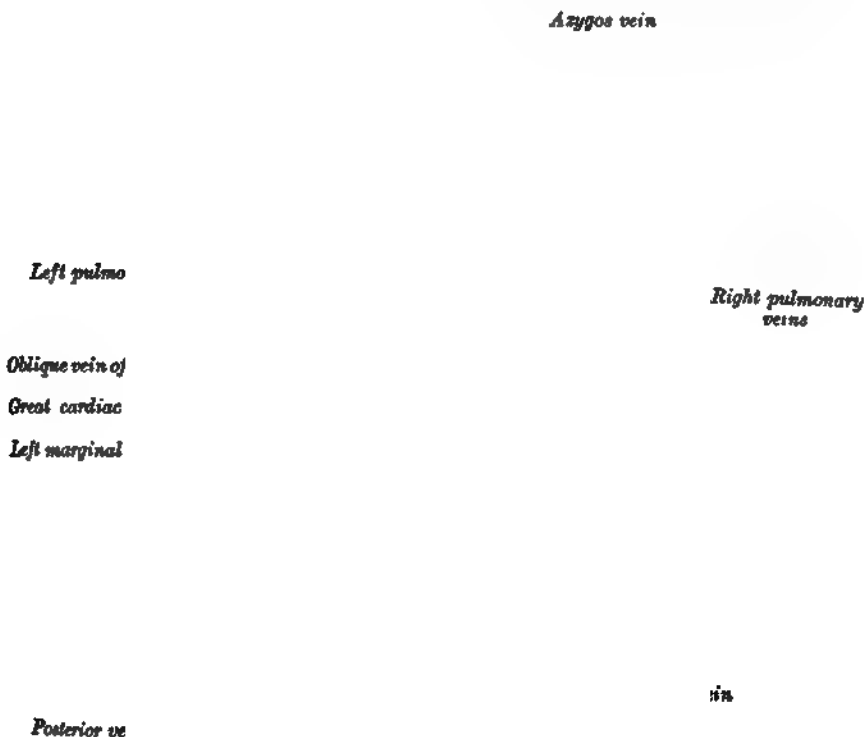

FIG. 573.—Base and diaphragmatic surface of heart.

and is bounded below by the posterior part of the coronary sulcus, containing the coronary sinus. On the right it is limited by the sulcus terminalis of the right atrium, and on the left by the ligament of the left vena cava and the oblique vein of the left atrium. The four pulmonary veins, two on either side, open into the left atrium, while the superior vena cava opens into the upper, and the anterior vena cava into the lower, part of the right atrium.

The **Apex** (*apex cordis*).—The apex is directed downward, forward, and to the left, and is overlapped by the left lung and pleura: it lies behind the fifth left intercostal space, 8 to 9 cm. from the mid-sternal line, or about 4 cm. below and 2 mm. to the medial side of the left mammary papilla.

The **sternocostal surface** (Fig. 574) is directed forward, upward, and to the left. Its lower part is convex, formed chiefly by the right ventricle, and traversed near its left margin by the anterior longitudinal sulcus. Its upper part is separated from

the lower by the coronary sulcus, and is formed by the atria; it presents a deep concavity (Fig. 576), occupied by the ascending aorta and the pulmonary artery.

The **diaphragmatic surface** (Fig. 573), directed downward and slightly backward, is formed by the ventricles, and rests upon the central tendon and a small part of the left muscular portion of the Diaphragma. It is separated from the base by the posterior part of the coronary sulcus, and is traversed obliquely by the posterior longitudinal sulcus.

The **right margin** of the heart is long, and is formed by the right atrium above and the right ventricle below. The atrial portion is rounded and almost vertical; it is situated behind the third, fourth, and fifth right costal cartilages about 1.25 cm. from the margin of the sternum. The ventricular portion, thin and sharp, is named the **acute margin**; it is nearly horizontal, and extends from the sternal end of the sixth right costal cartilage to the apex of the heart.

The **left or obtuse margin** is shorter, full, and rounded: it is formed mainly by the left ventricle, but to a slight extent, above, by the left atrium. It extends from a point in the second left intercostal space, about 2.5 mm. from the sternal margin, obliquely downward, with a convexity to the left, to the apex of the heart.

FIG. 574.—Sternocostal surface of heart.

Right Atrium (*atrium dextrum; right auricle*).—The right atrium is larger than the left, but its walls are somewhat thinner, measuring about 2 mm.; its cavity is capable of containing about 57 c.c. It consists of two parts: a principal cavity, or **sinus venarum**, situated posteriorly, and an anterior, smaller portion, the **auricula**.

Sinus Venarum (*sinus venosus*).—The sinus venarum is the large quadrangular cavity placed between the two venæ cavæ. Its walls, which are extremely thin, are connected below with the right ventricle, and medially with the left atrium, but are free in the rest of their extent.

Auricula (*auricula dextra; right auricular appendix*).—The auricula is a small conical muscular pouch, the margins of which present a dentated edge. It projects from the upper and front part of the sinus forward and toward the left side, overlapping the root of the aorta.

The separation of the auricula from the sinus venarum is indicated externally by a groove, the **terminal sulcus**, which extends from the front of the superior vena cava to the front of the inferior vena cava, and represents the line of union of the sinus venosus of the embryo with the primitive atrium. On the inner wall of the atrium the separation is marked by a vertical, smooth, muscular ridge, the **terminal crest**. Behind the crest the internal surface of the atrium is smooth, while in front of it the muscular fibres of the wall are raised into parallel ridges resembling the teeth of a comb, and hence named the **musculi pectinati**.

Dissection.—To examine the interior of the auricula, an incision should be made along its right border from the entrance of the superior vena cava to that of the inferior vena cava. A second cut is to be made from the centre of the first incision to the tip of the auricula dextra, and the flap raised.

FIG. 575.—Interior of right side of heart.

Its interior (Fig. 575) presents the following parts for examination:

Openings	{	Superior vena cava.	Valves	{	Valve of the inferior vena cava.
		Inferior vena cava.			Valve of the coronary sinus.
		Coronary sinus.			
		Foramina venarum minimarum.			
		Atrioventricular.			

Fossa ovalis.
Limbus fossae ovalis.
Intervenous tubercle.
Musculi pectinati.
Crista terminalis.

The **superior vena cava** returns the blood from the upper half of the body, and opens into the upper and back part of the atrium, the direction of its orifice being downward and forward. Its opening has no valve.

The **inferior vena cava**, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the atrium, near the atrial septum, its orifice being directed upward and backward, and guarded by

a rudimentary valve, the **valve of the inferior vena cava** (*Eustachian valve*). The blood entering the atrium through the superior vena cava is directed downward and forward, i. e., toward the atrioventricular orifice, while that entering through the inferior vena cava is directed upward and backward, toward the atrial septum. This is the normal direction of the two currents in fetal life.

The **coronary sinus** opens into the atrium, between the orifice of the inferior vena cava and the atrioventricular opening. It returns blood from the substance of the heart and is protected by a semicircular valve, the **valve of the coronary sinus** (*valve of Thebesius*).

The **foramina venarum minimarum** (*foramina Thebesii*) are the orifices of minute veins (*venae cordis minimae*), which return blood directly from the muscular substance of the heart.

The **atrioventricular opening** (*tricuspid orifice*) is the large oval aperture of communication between the atrium and the ventricle; it will be described with the right ventricle.

The **valve of the inferior vena cava** (*valvula venae cavae inferioris* [*Eustachii*]; *Eustachian valve*) is situated in front of the orifice of the inferior vena cava. It is semilunar in form, its convex margin being attached to the anterior margin of the orifice; its concave margin, which is free, ends in two cornua, of which the left is continuous with the anterior edge of the limbus fossae ovalis while the right is lost on the wall of the atrium. The valve is formed by a duplicature of the lining membrane of the atrium, containing a few muscular fibres. *In the fetus* this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left atrium. *In the adult* it occasionally persists, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and may present a cribriform or filamentous appearance; sometimes it is altogether wanting.

The **valve of the coronary sinus** (*valvula sinus coronarii* [*Thebesii*]; *Thebesian valve*) is a semicircular fold of the lining membrane of the atrium, at the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the atrium. This valve may be double or it may be cribriform.

The **fossa ovalis** is an oval depression on the septal wall of the atrium, and corresponds to the situation of the foramen ovale in the fetus. It is situated at the lower part of the septum, above and to the left of the orifice of the inferior vena cava.

The **limbus fossae ovalis** (*annulus ovalis*) is the prominent oval margin of the fossa ovalis. It is most distinct above and at the sides of the fossa; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa, leading upward beneath the limbus, into the left atrium; it is the remains of the fetal aperture between the two atria.

The **intervenous tubercle** (*tuberculum intervenosum*; *tubercle of Lower*) is a small projection on the posterior wall of the atrium, above the fossa ovalis. It is distinct in the hearts of quadrupeds, but in man is scarcely visible. It was supposed by Lower to direct the blood from the superior vena cava toward the atrioventricular opening.

Right Ventricle (*ventriculus dexter*).—The right ventricle is triangular in form, and extends from the right atrium to near the apex of the heart. Its antero-superior surface is rounded and convex, and forms the larger part of the sternocostal surface of the heart. Its under surface is flattened, rests upon the Diaphragma, and forms a small part of the diaphragmatic surface of the heart. Its posterior wall is formed by the ventricular septum, which bulges into the right ventricle, so that a transverse section of the cavity presents a semilunar outline. Its upper and left angle forms a conical pouch, the **conus arteriosus**, from which the pulmonary artery arises. A tendinous band, which may be named the *tendon of the conus arteriosus*, extends upward from the right atrioventricular fibrous

ring and connects the posterior surface of the conus arteriosus to the aorta. The wall of the right ventricle is thinner than that of the left, the proportion between them being as 1 to 3; it is thickest at the base, and gradually becomes thinner toward the apex. The cavity equals in size that of the left ventricle, and is capable of containing about 85 c.c.

Dissection.—To examine the interior of the right ventricle, its anterior wall should be turned downward and to the right in the form of a triangular flap. This is accomplished by making two incisions: (1) From the pulmonary artery to the apex of the ventricle parallel to, but a little to the right of, the anterior interatrial groove; (2) another, starting from the upper extremity, of the first and carried outward parallel to, but a little below, the atrioventricular groove, care being taken not to injure the atrioventricular opening.

Its interior (Fig. 575) presents the following parts for examination:

Openings	{ Right atrioventricular. Pulmonary artery.	Valves	{ Tricuspid. Pulmonary.
Trabeculae carneae.		Chordae tendineae.	

The **right atrioventricular orifice** is the large oval aperture of communication between the right atrium and ventricle. Situated at the base of the ventricle, it measures about 4 cm. in diameter and is surrounded by a fibrous ring, covered by the lining membrane of the heart; it is considerably larger than the corresponding aperture on the left side, being sufficient to admit the ends of four fingers. It is guarded by the tricuspid valve.

2

Left pulmonary veins

FIG. 576.—Heart seen from above.

FIG. 577.—Base of ventricles exposed by removal of the atria.

The opening of the pulmonary artery is circular in form, and situated at the summit of the conus arteriosus, close to the ventricular septum. It is placed above and to the left of the atrioventricular opening, and is guarded by the pulmonary semilunar valves.

The **tricuspid valve** (*valvula tricuspidalis*) (Figs. 575, 577) consists of three somewhat triangular cusps or segments. The largest cusp is interposed between the atrioventricular orifice and the conus arteriosus and is termed the **anterior or infundibular cusp**. A second, the **posterior or marginal cusp**, is in relation to the right margin of the ventricle, and a third, the **medial or septal cusp**, to the ventricular septum. They are formed by duplicatures of the lining membrane of the heart, strengthened

by intervening layers of fibrous tissue: their central parts are thick and strong, their marginal portions thin and translucent, and in the angles between the latter small intermediate segments are sometimes seen. Their bases are attached to a fibrous ring surrounding the atrioventricular orifice and are also joined to each other so as to form a continuous annular membrane, while their apices project into the ventricular cavity. Their atrial surfaces, directed toward the blood current from the atrium, are smooth; their ventricular surfaces, directed toward the wall of the ventricle, are rough and irregular, and, together with the apices and margins of the cusps, give attachment to a number of delicate tendinous cords, the **chordae tendineae**.

The **trabeculae carneae** (*columnae carneae*) are rounded or irregular muscular columns which project from the whole of the inner surface of the ventricle, with the exception of the conus arteriosus. They are of three kinds: some are attached along their entire length on one side and merely form prominent ridges, others are fixed at their extremities but free in the middle, while a third set (*musculi papillares*) are continuous by their bases with the wall of the ventricle, while their apices give origin to the chordae tendineae which pass to be attached to the segments of the tricuspid valve. There are two papillary muscles, anterior and posterior: of these, the anterior is the larger, and its chordae tendineae are connected with the anterior and posterior cusps of the valve: the posterior papillary muscle sometimes consists of two or three parts; its chordae tendineae are connected with the posterior and medial cusps. In addition to these, some chordae tendineae spring directly from the ventricular septum, or from small papillary eminences on it, and pass to the anterior and medial cusps. A muscular band, well-marked in sheep and some other animals, frequently extends from the base of the anterior papillary muscle to the ventricular septum. From its attachments it may assist in preventing overdistension of the ventricle, and so has been named the **moderator band**.

The **pulmonary semilunar valves** (Fig. 576) are three in number, two in front and one behind, formed by duplicatures of the lining membrane, strengthened by fibrous tissue. They are attached, by their convex margins, to the wall of the artery, at its junction with the ventricle, their free borders being directed upward into the lumen of the vessel. The free and attached margins of each are strengthened by tendinous fibres, and the former presents, at its middle, a thickened nodule (*corpus Arantii*). From this nodule tendinous fibres radiate through the segment to its attached margin, but are absent from two narrow crescentic portions, the **lunulae**, placed one on either side of the nodule immediately adjoining the free margin. Between the semilunar valves and the wall of the pulmonary artery are three **pouches or sinuses** (*sinuses of Valsalva*).

Dissection.—In order to examine the interior of the left atrium, make an incision on the posterior surface of the atrium from the pulmonary veins on one side to those on the other, the incision being carried a little way into the vessels. Make another incision from the middle of the horizontal one to the auricula sinistra.

Left Atrium (*atrium sinistum; left auricle*).—The left atrium is rather smaller than the right, but its walls are thicker, measuring about 3 mm.; it consists, like the right, of two parts, a **principal cavity** and an **auricula**.

The **principal cavity** is cuboidal in form, and concealed, in front, by the pulmonary artery and aorta; in front and to the right it is separated from the right atrium by the atrial septum; opening into it on either side are the two pulmonary veins.

Auricula (*auricula sinistra; left auricular appendix*).—The auricula is somewhat constricted at its junction with the principal cavity; it is longer, narrower, and more curved than that of the right side, and its margins are more deeply indented. It is directed forward and toward the right and overlaps the root of the pulmonary artery.

The interior of the left atrium (Fig. 578) presents the following parts for examination:

Openings of the four pulmonary veins.
Left atrioventricular opening.
Musculi pectinati.

The **pulmonary veins**, four in number, open into the upper part of the posterior surface of the left atrium—two on either side of its middle line: they are not provided with valves. The two left veins frequently end by a common opening.

The **left atrioventricular opening** is the aperture between the left atrium and ventricle, and is rather smaller than the corresponding opening on the right side.

The **musculi pectinati**, fewer and smaller than in the right auricula, are confined to the inner surface of the auricula.

On the atrial septum may be seen a lunated impression, bounded below by a crescentic ridge, the concavity of which is turned upward. The depression is just above the fossa ovalis of the right atrium.

FIG. 578.—Interior of left side of heart.

Dissection.—To examine the interior of the left ventricle, make an incision a little to the left of the anterior interatrial groove from the base to the apex of the heart, and carry it up from thence, a little to the left of the posterior interatrial groove, nearly as far as the atrioventricular groove.

Left Ventricle (*ventriculus sinister*).—The left ventricle is longer and more conical in shape than the right, and on transverse section its concavity presents an oval or nearly circular outline. It forms a small part of the sternocostal surface and a considerable part of the diaphragmatic surface of the heart; it also forms the apex of the heart. Its walls are about three times as thick as those of the right ventricle.

Its interior (Fig. 578) presents the following parts for examination:

Openings { Left atrioventricular.
 { Aortic. \angle
Trabeculae carneae.

Valves { Bicuspid or Mitral.
 { Aortic.
Chordae tendineae.

The **left atrioventricular opening** (*mitral orifice*) is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side, admitting only two fingers. It is surrounded by a dense fibrous ring, covered by the lining membrane of the heart, and is guarded by the bicuspid or mitral valve.

The **aortic opening** is a circular aperture, in front and to the right of the atrioventricular, from which it is separated by the anterior cusp of the bicuspid valve. Its orifice is guarded by the **aortic semilunar valves**. The portion of the ventricle immediately below the aortic orifice is termed the **aortic vestibule**, and possesses fibrous instead of muscular walls.

The **bicuspid or mitral valve** (*valvula bicuspidalis* [*metralis*]) (Figs. 577, 578) is attached to the circumference of the left atrioventricular orifice in the same way that the tricuspid valve is on the opposite side. It consists of two triangular cusps, formed by duplicatures of the lining membrane, strengthened by fibrous tissue, and containing a few muscular fibres. The cusps are of unequal size, and are larger, thicker, and stronger than those of the tricuspid valve. The larger cusp is placed in front and to the right between the atrioventricular and aortic orifices, and is known as the **anterior or aortic cusp**; the smaller or **posterior cusp** is placed behind and to the left of the opening. Two smaller cusps are usually found at the angles of junction of the larger. The cusps of the bicuspid valve are furnished with chordae tendineae, which are attached in a manner similar to those on the right side; they are, however, thicker, stronger, and less numerous.

FIG. 579.—Aorta laid open to show the semilunar valves.

The **aortic semilunar valves** (Figs. 576, 579) are three in number, and surround the orifice of the aorta; two are posterior (right and left) and one anterior. They are similar in structure, and in their mode of attachment, to the pulmonary semilunar valves, but are larger, thicker, and stronger; the lunulae are more distinct, and the noduli or corpora Arantii thicker and more prominent. Opposite the valves the aorta presents slight dilatations, the **aortic sinuses** (*sinuses of Valsalva*), which are larger than those at the origin of the pulmonary artery.

The **trabeculae carneae** are of three kinds, like those upon the right side, but they are more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall of the ventricle. The **musculi papillares** are two in number, one being connected to the anterior, the other to the posterior wall; they are of large size, and end in rounded extremities from which the chordae tendineae arise. The chordae tendineae from each papillary muscle are connected to both cusps of the bicuspid valve.

Ventricular Septum (*septum ventriculorum; interventricular septum*) (Fig. 580).—The ventricular septum is directed obliquely backward and to the right, and is curved with the convexity toward the right ventricle: its margins correspond with the anterior and posterior longitudinal sulci. The greater portion of it is thick and muscular and constitutes the **muscular ventricular septum**, but its upper and posterior part, which separates the aortic vestibule from the lower part of the right atrium and upper part of the right ventricle, is thin and fibrous, and is termed the **membranous ventricular septum**. An abnormal communication may exist between the ventricles at this part owing to defective development of the membranous septum.

Structure.—The heart consists of muscular fibres, and of fibrous rings which serve for their attachment. It is covered by the visceral layer of the serous pericardium (**epicardium**), and lined by the **endocardium**. Between these two membranes is the muscular wall or **myocardium**.

The **endocardium** is a thin, smooth membrane which lines and gives the glistening appearance to the inner surface of the heart; it assists in forming the valves by its reduplications, and is continuous with the lining membrane of the large bloodvessels. It consists of connective tissue and elastic fibres, and is attached to the muscular structure by loose elastic tissue which contains bloodvessels and nerves; its free surface is covered by endothelial cells.

FIG. 580.—Section of the heart showing the ventricular septum.

The **fibrous rings** surround the atrioventricular and arterial orifices, and are stronger upon the left than on the right side of the heart. The atrioventricular rings serve for the attachment of the muscular fibres of the atria and ventricles, and for the attachment of the bicuspid and tricuspid valves. The left atrioventricular ring is closely connected, by its right margin, with the aortic arterial ring; between these and the right atrioventricular ring is a triangular mass of fibrous tissue, the **trigonum fibrosum**, which represents the *os cordis* seen in the heart of some of the larger animals, as the ox and elephant. Lastly, there is the tendinous band, already referred to (p. 608), on the posterior surface of the conus arteriosus.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of some of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, to which the middle coat of the artery is firmly fixed. The attachment of the artery to its fibrous ring is strengthened by the external coat and serous membrane externally, and

by the endocardium internally. From the margins of the semicircular notches the fibrous structure of the ring is continued into the segments of the valves. The middle coat of the artery in this situation is thin, and the vessel is dilated to form the sinuses of the aorta and pulmonary artery.

The **muscular structure of the heart** consists of bands of fibres, which present an exceedingly intricate interlacement. They comprise (a) the fibres of the atria, (b) the fibres of the ventricles, and (c) the atrioventricular bundle of His.

The **fibres of the atria** are arranged in two layers—a superficial, common to both cavities, and a deep, proper to each. The **superficial fibres** are most distinct on the front of the atria, across the bases of which they run in a transverse direction, forming a thin and incomplete layer. Some of these fibres run into the atrial septum. The **deep fibres** consist of looped and annular fibres. The *looped fibres* pass upward over each atrium, being attached by their two extremities to the corresponding atrioventricular ring, in front and behind. The *annular fibres* surround the auriculæ, and form annular bands around the terminations of the veins and around the fossa ovalis.

The **fibres of the ventricles** are arranged in a complex manner, and various accounts have been given of their course and connections; the following description is based on the work of McCallum.¹ They consist of superficial and deep layers, all of which, with the exception of two, are inserted into the papillary muscles of the ventricles. The **superficial layers** consist of the following: (a) Fibres which spring from the tendon of the conus arteriosus and sweep downward and toward the left across the anterior longitudinal sulcus and around the apex of the heart, where they pass upward and inward to terminate in the papillary muscles of the left ventricle; those arising from the upper half of the tendon of the conus arteriosus pass to the anterior papillary muscle, those from the lower half to the posterior papillary muscle and the papillary muscles of the septum. (b) Fibres which arise from the right atrioventricular ring and run diagonally across the diaphragmatic surface of the right ventricle and around its right border on to its costosternal surface, where they dip beneath the fibres just described, and, crossing the anterior longitudinal sulcus, wind around the apex of the heart and end in the posterior papillary muscle of the left ventricle. (c) Fibres which spring from the left atrioventricular ring, and, crossing the posterior longitudinal sulcus, pass successively into the right ventricle and end in its papillary muscles. The **deep layers** are three in number; they arise in the papillary muscles of one ventricle and, curving in an S-shaped manner, turn in at the longitudinal sulcus and end in the papillary muscles of the other ventricle. The layer which is most superficial in the right ventricle lies next the lumen of the left, and *vice versa*. Those of the first layer almost encircle the right ventricle and, crossing in the septum to the left, unite with the superficial fibres from the right atrioventricular ring to form the posterior papillary muscle. Those of the second layer have a less extensive course in the wall of the right ventricle, and a correspondingly greater course in the left, where they join with the superficial fibres from the anterior half of the tendon of the conus arteriosus to form the papillary muscles of the septum. Those of the third layer pass almost entirely around the left ventricle and unite with the superficial fibres from the lower half of the tendon of the conus arteriosus to form the anterior papillary muscle. Besides the layers just described there are two bands which do not end in papillary muscles. One springs from the right atrioventricular ring and crosses in the atrioventricular septum; it then encircles the deep layers of the left ventricle and ends in the left atrioventricular ring. The second band is apparently confined to the left ventricle; it is attached to the left atrioventricular ring, and encircles the portion of the ventricle adjacent to the aortic orifice.

The **atrioventricular bundle of His** is the only direct muscular connection known to exist between the atria and the ventricles. It arises in connection with two small collections of spindle-shaped cells, the sinoatrial and atrioventricular nodes. The **sinoatrial node** is situated on the anterior border of the opening of the superior vena cava; from it strands of fusiform fibres run under the endocardium of the wall of the atrium to the atrioventricular node. The **atrioventricular node** lies near the orifice of the coronary sinus in the annular and septal fibres of the right atrium; from it the atrioventricular bundle passes forward in the lower part of the membranous septum, and divides into right and left fasciculi. These run down in the right and left ventricles, one on either side of the ventricular septum, covered by endocardium. In the lower parts of the ventricles they break up into numerous strands which end in the papillary muscles and in the ventricular muscle generally. The greater portion of the atrioventricular bundle consists of narrow, somewhat fusiform fibres, but its terminal strands are composed of Purkinje fibres.

Dr. A. Morison² has shown that in the sheep and pig the atrioventricular bundle "is a great avenue for the transmission of nerves from the auricular to the ventricular heart; large and numerous nerve trunks entering the bundle and coursing with it." From these, branches pass off and form plexuses around groups of Purkinje cells, and from these plexuses fine fibrils go to innervate individual cells.

Applied Anatomy.—Clinical and experimental evidence go to prove that this bundle conveys the impulse to systolic contraction from the atrial septum to the ventricles, and much attention has recently been paid to it, because it appears to become fibrosed and to lose much of its

¹ Johns Hopkins Hospital Reports, vol. ix.

² Journal of Anatomy and Physiology, vol. xlv.

conducting power (heart-block) in many cases of Stokes-Adams' disease. This condition is characterized by a slow pulse, a tendency to syncopal or epileptiform seizures, and the fact that while the cardiac atria beat at a normal rate, the ventricles contract much less frequently.

Vessels and Nerves.—The **arteries** supplying the heart are the right and left coronary from the aorta; the **veins** end in the right atrium.

The **lymphatics** end in the thoracic and right lymphatic ducts.

The **nerves** are derived from the cardiac plexus, which are formed partly from the vagi, and partly from the sympathetic trunks. They are freely distributed both on the surface and in the substance of the heart, the separate nerve filaments being furnished with small ganglia.

The Cardiac Cycle and the Actions of the Valves.—By the contractions of the heart the blood is pumped through the arteries to all parts of the body. These contractions occur regularly and at the rate of about seventy per minute. Each wave of contraction or *period of activity* is followed by a *period of rest*, the two periods constituting what is known as a **cardiac cycle**.

Each cardiac cycle consists of three phases, which succeed each other as follows: (1) a short simultaneous contraction of both atria, termed the **atrial systole**, followed, after a slight pause, by (2) a simultaneous, but more prolonged, contraction of both ventricles, named the **ventricular systole**, and (3) a **period of rest**, during which the whole heart is relaxed. The atrial contraction commences around the venous openings, and sweeping over the atria forces their contents through the atrio-ventricular openings into the ventricles, regurgitation into the veins being prevented by the contraction of their muscular coats. When the ventricles contract, the tricuspid and bicuspid valves are closed, and prevent the passage of the blood back into the atria; the muscoli papillares at the same time are shortened, and, pulling on the chordae tendineae, prevent the inversion of the valves into the atria. As soon as the pressure in the ventricles exceeds that in the pulmonary artery and aorta, the valves guarding the orifices of these vessels are opened and the blood is driven from the right ventricle into the pulmonary artery and from the left into the aorta. The moment the systole of the ventricles ceases, the pressure of the blood in the pulmonary artery and aorta closes the pulmonary and aortic semilunar valves to prevent regurgitation of blood into the ventricles, the valves remaining shut until reopened by the next ventricular systole. During the period of rest the tension of the tricuspid and bicuspid valves is relaxed, and blood is flowing from the veins into the atria, being aspirated by negative intrathoracic pressure, and slightly also from the atria into the ventricles. The average duration of a cardiac cycle is about $\frac{8}{10}$ of a second, made up as follows:

Atrial systole, $\frac{1}{10}$.

Atrial diastole, $\frac{7}{10}$.

Ventricular systole, $\frac{3}{10}$.

Ventricular diastole, $\frac{5}{10}$.

Total systole, $\frac{4}{10}$.

Complete diastole, $\frac{4}{10}$.

The rhythmical action of the heart is *muscular* in origin—that is to say, the heart muscle itself possesses the inherent property of contraction apart from any nervous stimulation. The more embryonic the muscle the better is it able to initiate and propagate the contraction wave; this explains why the normal systole of the heart starts at the entrance of the veins, for there the muscle is most embryonic in nature. At the atrioventricular junction there is a slight pause in the wave of muscular contraction. To obviate this as far as possible a peculiar band of marked embryonic type passes across the junction and so carries on the contraction wave to the ventricles. This band, composed of special fibres, is the atrioventricular bundle of His (p. 614). The nerves, although not concerned in originating the contractions of the heart muscle, play an important role in regulating their force and frequency in order to subserve the physiological needs of the organism.

Applied Anatomy.—Wounds of the heart are often immediately fatal, but not necessarily so. They may be non-penetrating, when death may occur from hemorrhage if one of the coronary vessels has been wounded, or subsequently from pericarditis. Even a penetrating wound is not necessarily fatal, as a considerable number of cases have been recorded in which the wound has been sutured successfully.

PECULIARITIES IN THE VASCULAR SYSTEM OF THE FETUS.

The development of the heart and vascular system is described on pages 141 to 162.

The chief peculiarities of the fetal heart are the direct communication between the atria through the foramen ovale, and the large size of the valve of the inferior vena cava. Among other peculiarities the following may be noted. (1) In early fetal life the heart lies immediately below the mandibular arch, and as development proceeds it is gradually drawn within the thorax. (2) For a time the atrial portion exceeds the ventricular in size, and the walls of the ventricles are of equal thickness: toward the end of fetal life the ventricular portion becomes the larger and the wall of the left ventricle exceeds that of the right in thickness. (3) Its size is large as compared with that of the rest of the body, the proportion at the second month being 1 to 50, and at birth, 1 to 120, while in the adult the average is about 1 to 160.

The **foramen ovale**, situated at the lower part of the atrial septum, forms a free communication between the atria until the end of fetal life. A septum (*septum secundum*) grows down from the upper wall of the atrium to the right of the primary septum in which the foramen ovale is situated; shortly after birth it fuses with the primary septum and the foramen ovale is obliterated.

The **valve of the inferior vena cava** serves to direct the blood from that vessel through the foramen ovale into the left atrium.

The peculiarities in the arterial system of the fetus are the communication between the pulmonary artery and the aorta by means of the ductus arteriosus, and the continuation of the hypogastric arteries as the umbilical arteries to the placenta.

The **ductus arteriosus** is a short tube, about 1.25 cm. in length at birth, and of the diameter of a goose-quill. In the early condition it forms the continuation of the pulmonary artery, and opens into the aorta, just beyond the origin of the left subclavian artery; and so conducts the greater amount of the blood from the right ventricle into the aorta. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery.

The **hypogastric arteries** run along the sides of the bladder and thence upward on the back of the anterior abdominal wall to the umbilicus; here they pass out of the abdomen and are continued as the **umbilical arteries** in the umbilical cord to the placenta. They convey the fetal blood to the placenta.

The peculiarities in the venous system of the fetus are the communications established between the placenta and the liver and portal vein, through the umbilical vein; and between the umbilical vein and the inferior vena cava through the ductus venosus.

Fetal Circulation (Fig. 581).—The fetal blood is returned from the placenta to the fetus by the umbilical vein. This vein enters the abdomen at the umbilicus, and passes upward along the free margin of the falciform ligament of the liver to the under surface of that organ, where it gives off two or three branches, one of large size to the left lobe, and others to the lobus quadratus and lobus caudatus. At the **porta hepatis** (*transverse fissure of the liver*) it divides into two branches: of these, the larger is joined by the portal vein, and enters the right lobe; the smaller is continued upward, under the name of the **ductus venosus**, and joins the inferior vena cava. The blood, therefore, which traverses the umbilical vein, passes to the inferior vena cava in three different ways. A considerable quantity circulates through the liver with the portal venous blood, before entering the inferior vena cava by the hepatic veins; some enters the liver directly, and is

carried to the inferior cava by the hepatic veins; the remainder passes directly into the inferior vena cava through the ductus venosus.

In the inferior vena cava, the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and abdominal

arteries

FIG. 581.—Plan of the fetal circulation. In this plan the figured arrows represent the kind of blood, as well as the direction which it takes in the vessels. Thus—arterial blood is figured \rightarrow ; venous blood, \leftarrow ; mixed (arterial and venous) blood, \rightarrow .

wall. It enters the right atrium, and, guided by the valve of the inferior vena cava, passes through the foramen ovale into the left atrium, where it mixes with a small quantity of blood returned from the lungs by the pulmonary veins. From the left atrium it passes into the left ventricle; and from the left ventricle into the aorta, by means of which it is distributed almost entirely to the head and upper

extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the superior vena cava to the right atrium, where it mixes with a small portion of the blood from the inferior vena cava. From the right atrium it descends into the right ventricle, and thence passes into the pulmonary artery. The lungs of the fetus being inactive, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and returned by the pulmonary veins to the left atrium: the greater part passes through the ductus arteriosus into the aorta, where it mixes with a small quantity of the blood transmitted by the left ventricle into the aorta. Through this vessel it descends, and is in part distributed to the lower extremities and the viscera of the abdomen and pelvis, but the greater amount is conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fetus the following facts will be evident: (1) The placenta serves the purposes of nutrition and excretion, receiving the impure blood from the fetus, and returning it purified and charged with additional nutritive material. (2) Nearly the whole of the blood of the umbilical vein traverses the liver before entering the inferior vena cava; hence the large size of the liver, especially at an early period of fetal life. (3) The right atrium is the point of meeting of a double current, the blood in the inferior vena cava being guided by the valve of this vessel into the left atrium, while that in the superior vena cava descends into the right ventricle. At an early period of fetal life it is highly probable that the two streams are quite distinct; for the inferior vena cava opens almost directly into the left atrium, and the valve of the inferior vena cava would exclude the current from the right ventricle. At a later period, as the separation between the two atria becomes more distinct, it seems probable that some mixture of the two streams must take place. (4) The pure blood carried from the placenta to the fetus by the umbilical vein, mixed with the blood from the portal vein and inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities. (5) The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and limbs, together with a small quantity from the left ventricle, is distributed to the abdomen and lower extremities.

Changes in the Vascular System at Birth.—At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, and the placental circulation is cut off. The foramen ovale is closed by about the tenth day after birth: the valvular fold above mentioned adheres to the margin of the foramen for the greater part of its circumference, but a slit-like opening is left between the two atria above, and this sometimes persists.

The **ductus arteriosus** begins to contract immediately after respiration is established, and is completely closed from the fourth to the tenth day; it ultimately degenerates into an impervious cord, the **ligamentum arteriosum**, which connects the left pulmonary artery to the arch of the aorta.

Of the **hypogastric arteries**, the parts extending from the sides of the bladder to the umbilicus become obliterated between the second and fifth days after birth, and project as fibrous cords, the **lateral umbilical ligaments**, toward the abdominal cavity, carrying on them folds of peritoneum.

The **umbilical vein** and **ductus venosus** are completely obliterated between the second and fifth days after birth; the former becomes the **ligamentum teres**, the latter the **ligamentum venosum**, of the liver.

THE ARTERIES.

THE distribution of the systematic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle, while the smallest ramifications extend to the peripheral parts of the body and the contained organs. Arteries are found in all parts of the body, except in the hairs, nails, epidermis, cartilages, and cornea; the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor surface, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as may be observed in the coeliac artery and the thyrocervical trunk: the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs; or the division may be dichotomous, as, for instance, when the aorta divides into the two common iliacs.

A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined sectional area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined sectional area of all the arterial branches greatly exceeds that of the aorta; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, and the base to the capillary system.

The arteries, in their distribution, communicate with one another, forming what are called **anastomoses**, and these communications are very free between the large as well as between the smaller branches. The anastomosis between trunks of equal size is found where great activity of the circulation is requisite, as in the brain; here the two vertebral arteries unite to form the basilar, and the two anterior cerebral arteries are connected by a short communicating trunk; it is also found in the abdomen, where the intestinal arteries have very ample anastomoses between their larger branches. In the limbs the anastomoses are most numerous and of largest size around the joints, the branches of an artery above uniting with branches from the vessels below. These anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a **collateral circulation** is established after the application of a ligature to an artery. The smaller branches of arteries anastomose more frequently than the larger; and between the smallest twigs these anastomoses become so numerous as to constitute a close network that pervades nearly every tissue of the body.

Throughout the body generally the larger arterial branches pursue a fairly straight course, but in certain situations they are tortuous. Thus the external maxillary artery in its course over the face, and the arteries of the lips, are extremely tortuous to accommodate themselves to the movements of the parts. The uterine arteries are also tortuous, to accommodate themselves to the increase of size which the uterus undergoes during pregnancy.

Applied Anatomy.—All the arteries, and most of all the aorta, are liable to a degenerative process known as atheroma, arteriosclerosis, or, more recently, atherosclerosis (Marchand), that is of the greatest clinical importance. It is essentially a senile change, although it may begin at any age and is predisposed to by renal disease, gout, diabetes mellitus, lead poisoning, and a number of other morbid states, and results in the replacement of the arterial elastic tissue by

fibrous tissue. Its chief ill effects are two. In the first place, it is associated with a permanent and often considerable rise in the arterial blood pressure, entailing a corresponding hypertrophy of the heart; in the second, it weakens the vessel walls, rendering them more liable to rupture, while at the same time it is apt to lessen the calibre of the affected vessels.

The arteries are also frequently attacked by syphilis, which gives rise to inflammation and degeneration of their middle coats. Recent researches¹ go to prove that arterial aneurisms, other than those due to direct injury, occur almost solely in syphilitic patients.

Internal mammary vessels \

Thoracic duct *Vagus nerves*
FIG. 582.—Transverse section of thorax, showing relations of pulmonary artery

The Pulmonary Artery (*A. Pulmonalis*) (Fig. 582).

The **pulmonary artery** conveys the venous blood from the right ventricle of the heart to the lungs. It is a short, wide vessel, about 5 cm. in length and 3 cm. in diameter, *arising* from the conus arteriosus of the right ventricle. It extends obliquely upward and backward, passing at first in front and then to the left of the ascending aorta, as far as the under surface of the aortic arch, where it divides, about the level of the fibrocartilage between the fifth and sixth thoracic vertebræ, into right and left branches of nearly equal size.

Relations.—The whole of this vessel is contained within the pericardium. It is enclosed with the ascending aorta in a single tube of the visceral layer of the serous pericardium, which is continued upward upon them from the base of the heart. The fibrous layer of the pericardium is gradually lost upon the external coats of the two branches of the artery. In *front*, the pulmonary artery is separated from the anterior end of the second left intercostal space by the pleura and left lung, in addition to the pericardium; it rests at first upon the ascending aorta, and higher up lies in front of the left atrium on a plane posterior to the ascending aorta. On *either side* of its origin is the auricula of the corresponding atrium and a coronary artery, the left coronary artery passing, in the first part of its course, behind the vessel. The superficial part of the cardiac plexus lies above its bifurcation, between it and the arch of the aorta.

The **right branch of the pulmonary artery** (*ramus dexter a. pulmonalis*), longer and larger than the left, runs horizontally to the right, behind the ascending aorta and superior vena cava and in front of the right bronchus, to the root of the right

¹ C. U. Atchison, Archives of the Pathological Institute of the London Hospital, 1906, ii, 1.

lung, where it divides into two branches. The lower and larger of these goes to the middle and lower lobes of the lung; the upper and smaller is distributed to the upper lobe.

The **left branch of the pulmonary artery** (*ramus sinister a. pulmonalis*), shorter and somewhat smaller than the right, passes horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches, one for each lobe of the lung.

Above, it is connected to the concavity of the aortic arch by the ligamentum arteriosum, on the left of which is the left recurrent nerve, and on the right the superficial part of the cardiac plexus. *Below*, it is joined to the upper left pulmonary vein by the ligament of the left vena cava (page 159).

The terminal branches of the pulmonary arteries will be described with the anatomy of the lungs.

Applied Anatomy.—Stenosis of the pulmonary artery, either with, or, more rarely, without defective formation of the ventricular septum, is one of the commonest congenital defects of the heart. It may be due either to fetal endocarditis, or to maldevelopment of the bulbus cordis (p. 149).¹ As in most forms of congenital heart disease, the child is cyanosed (*morbus caeruleus*), especially when excited or on exertion, and rarely lives to grow up, commonly dying of heart failure in infancy, or of pulmonary tuberculosis or intercurrent disease in childhood. The chief signs of the condition are the loud, harsh systolic cardiac murmur best heard over the second left costal cartilage, cyanosis, clubbing of the finger tips, and the presence of an excess of red corpuscles in the blood.

Embolism of the pulmonary artery by a clot of blood coming from the right side of the heart in patients with heart disease, or from a thrombosed vein in cases, for example, of influenza, enteric fever, puerperal sepsis, or fractured limbs, is a common cause of sudden or rapid death. The patient may cry out with sudden excruciating pain in the precordia when the detached embolus lodges, and after a brief period of intense dyspnoea, pallor, and anguish, die.

THE AORTA.

The **aorta** is the main trunk of a series of vessels which convey the oxygenated blood to the tissues of the body for their nutrition. It commences at the upper part of the left ventricle, where it is about 3 cm. in diameter, and after ascending for a short distance, arches backward and to the left side, over the root of the left lung; it then descends within the thorax on the left side of the vertebral column, passes into the abdominal cavity through the aortic hiatus in the Diaphragma, and ends, considerably diminished in size (about 1.75 cm. in diameter), opposite the lower border of the fourth lumbar vertebra, by dividing into the right and left common iliac arteries. Hence it is described in several portions, viz., the **ascending aorta**, the **arch of the aorta**, and the **descending aorta**, which last is again divided into the **thoracic** and **abdominal aortae**.

THE ASCENDING AORTA (AORTA ASCENDENS) (Fig. 583).

The **ascending aorta** is about 5 cm. in length. It commences at the upper part of the base of the left ventricle, on a level with the lower border of the third costal cartilage behind the left half of the sternum; it passes obliquely upward, forward, and to the right, in the direction of the heart's axis, as high as the upper border of the second right costal cartilage, describing a slight curve in its course, and being situated, about 6 cm. behind the posterior surface of the sternum. At its origin it presents, opposite the segments of the aortic valve, three small dilatations called the **aortic sinuses**. At the union of the ascending aorta with the aortic arch

¹ Keith (Studies in Pathology, Aberdeen University, 1906) believes that the great majority of cases which are classified as congenital stenosis of the pulmonary or of the aortic orifices are, in reality, due to an arrest of development or malformation of the bulbus cordis.

the calibre of the vessel is increased, owing to a bulging of its right wall. This dilatation is termed the **bulb of the aorta**, and on transverse section presents a somewhat oval figure. The ascending aorta is contained within the pericardium, and is enclosed in a tube of the serous pericardium, common to it and the pulmonary artery.

Relations.—The ascending aorta is covered at its commencement by the trunk of the pulmonary artery and the right auricle, and, higher up, is separated from the sternum by the pericardium, the right pleura, the anterior margin of the right lung, some loose areolar tissue, and the remains of the thymus; *posteriorly*, it rests upon the left atrium and right pulmonary artery. On the *right side*, it is in relation with the superior vena cava and right atrium, the former lying partly behind it; on the *left side*, with the pulmonary artery.

Left coronary
of the

FIG. 583.—The arch of the aorta, and its branches.

Branches.—The only branches of the ascending aorta are the two coronary arteries which supply the heart; they arise near the commencement of the aorta immediately above the attached margins of the semilunar valves.

The Coronary Arteries.—The **Right Coronary Artery** (*a. coronaria [cordis] dextra*) arises from the anterior aortic sinus. It passes at first between the conus arteriosus and the right auricle and then runs in the right portion of the coronary sulcus, coursing at first from the left to right and then on the diaphragmatic surface

of the heart from right to left as far as the posterior longitudinal sulcus, down which it is continued to the apex of the heart as the **posterior descending branch**. It gives off a large **marginal branch** which follows the acute margin of the heart and supplies branches to both surfaces of the right ventricle. It also gives twigs to the right atrium and to the part of the left ventricle which adjoins the posterior longitudinal sulcus.

The **Left Coronary Artery** (*a. coronaria [cordis] sinistra*), larger than the right, arises from the left posterior aortic sinus and divides into an anterior descending and a circumflex branch. The **anterior descending branch** passes at first behind the pulmonary artery and then comes forward between that vessel and the left auricula to reach the anterior longitudinal sulcus, along which it descends to the incisura apicis cordis; it gives branches to both ventricles. The **circumflex branch** follows the left part of the coronary sulcus, running first to the left and then to the right, reaching nearly as far as the posterior longitudinal sulcus; it gives branches to the left atrium and ventricle. There is a free anastomosis between the minute branches of the two coronary arteries in the substance of the heart.

Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three, the additional branch being of small size. More rarely, there are two additional branches.

Applied Anatomy.—The sudden blocking of a coronary artery by an embolus, or its more gradual obstruction by arterial disease or thrombosis, is a common cause of sudden death in persons past middle age. If the obstruction to the passage of blood is incomplete, true *angina pectoris* may occur. In this condition the patient is suddenly seized with a spasm of agonizing pain in the precordial region and down the left arm, together with an indescribable sense of anguish. He may die in such an attack, or succumb a few hours or days later from heart failure, or survive a number of attacks.

THE ARCH OF THE AORTA (ARCUS AORTAE; TRANSVERSE AORTA) (Fig. 583).

The **arch of the aorta** begins at the level of the upper border of the second sterno-costal articulation of the right side, and runs at first upward, backward, and to the left in front of the trachea; it is then directed backward on the left side of the trachea and finally passes downward on the left side of the body of the fourth thoracic vertebra, at the lower border of which it becomes continuous with the descending aorta. It thus forms two curvatures: one with its convexity upward, the other with its convexity forward and to the left. Its upper border is usually about 2.5 cm. below the superior border to the manubrium sterni.

Relations.—The arch of the aorta is covered *anteriorly* by the pleuræ and anterior margins of the lungs, and by the remains of the thymus. As the vessel runs backward its *left* side is in contact with the left lung and pleura. Passing downward on the left side of this part of the arch are four nerves; in order from before backward these are, the left phrenic, the lower of the superior cardiac branches of the left vagus, the superior cardiac branch of the left sympathetic, and the trunk of the left vagus. As the last nerve crosses the arch it gives off its recurrent branch, which hooks around below the vessel and then passes upward on its right side. The highest left inter-costal vein runs obliquely upward and forward on the left side of the arch, between the phrenic and vagus nerves. On the *right* are the deep part of the cardiac plexus, the left recurrent nerve, the œsophagus, and the thoracic duct; the trachea lies behind and to the right of the vessel. *Above* are the innominate, left common carotid, and left subclavian arteries, which arise from the convexity of the arch and are crossed close to their origins by the left innominate vein. *Below* are the bifurcation of the pulmonary artery, the left bronchus, the ligamentum arteriosum, the superficial part of the cardiac plexus, and the left recurrent nerve. As already stated, the ligamentum arteriosum connects the commencement of the left pulmonary artery to the aortic arch.

Between the origin of the left subclavian artery and the attachment of the ductus arteriosus the lumen of the fetal aorta is considerably narrowed, forming what is termed the **aortic isthmus**, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilation which His has named the **aortic spindle**—the

point of junction of the two parts being marked in the concavity of the arch by an indentation or angle. These conditions persist, to some extent, in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm.

Distinct from this diffuse and moderate stenosis at the isthmus is the condition known as *coarctation of the aorta*, or marked stenosis often amounting to complete obliteration of its lumen, seen in adults and occurring at or near, oftenest a little below, the insertion of the ligamentum arteriosum into the aorta. According to Bonnet¹ this coarctation is never found in the fetus or at birth, and is due to an abnormal extension of the peculiar tissue of the ductus into the aortic wall, which gives rise to a simultaneous stenosis of both vessels as it contracts after birth—the ductus is usually obliterated in these cases. An extensive collateral circulation is set up, by the costocervicals, internal mammaries, and the descending branches of the transverse cervical above the stenosis, and below it by the first four aortic intercostals, the pericardio-phrenics, and the superior and inferior epigastrics.

Peculiarities.—The height to which the aorta rises in the thorax is usually about 2.5 cm. below the upper border of the sternum; but it may ascend nearly to the top of the bone. Occasionally it is found 4 cm., more rarely from 5 to 8 cm. below this point. Sometimes the aorta arches over the root of the right lung (right aortic arch) instead of over that of the left, and passes down on the right side of the vertebral column, a condition which is found in birds. In such cases all the thoracic and abdominal viscera are transposed. Less frequently the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the vertebral column; this peculiarity is not accompanied by transposition of the viscera. The aorta occasionally divides, as in some quadrupeds, into an ascending and a descending trunk, the former of which is directed vertically upward, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides near its origin into two branches, which soon reunite. In one of these cases the oesophagus and trachea were found to pass through the interval between the two branches; this is the normal condition of the vessel in the reptilia.

Applied Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurism of this part.

Aneurism of the ascending aorta, in the situation of the aortic sinuses, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses takes place chiefly on the anterior aspect of the vessel. As the aneurismal sac enlarges, it may compress any or all of the structures in immediate proximity with it, but chiefly projects toward the right anterior side; and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. If it project forward, it may destroy the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumor on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress, or open into the right lung, the trachea, bronchi, or oesophagus. In the majority of cases it bursts into the cavity of the pericardium, the patient suddenly drops down dead, and, upon a postmortem examination, the pericardial sac is found full of blood; or it may compress the right atrium, or the pulmonary artery, and adjoining part of the right ventricle, and open into one or the other of these parts. It may press upon the superior vena cava or the innominate veins, causing great venous engorgement. The face becomes livid and swollen, the right arm and anterior thoracic wall cedematous, and the congestion of the brain gives rise to headache and vertigo. An aneurism has occasionally perforated into the superior vena cava, setting up an arteriovenous aneurism. When this happens the patient suddenly becomes very short of breath, intensely congested and cedematous in the face and upper part of the body, and develops a palpable thrill and a continuous humming murmur, loudest during systole, over the sternum. Death follows a few days or weeks after such a perforation; and somewhat similar symptoms are occasioned when an aortic aneurism erodes and bursts into the pulmonary artery.

Regarding the arch of the aorta, the student is reminded that the vessel lies against the trachea, oesophagus, and thoracic duct; that the recurrent nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. An aneurismal tumor taking origin from the posterior part of the vessel, its most usual site, may press upon the trachea and give rise to the sign known as *tracheal tugging*, impede the breathing, or produce cough, dyspnoea, bronchiectasis, hemoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hemorrhage. Again, its pressure on the left recurrent nerve may give rise to symptoms of laryngeal paralysis; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the oesophagus, producing dysphagia, and has not infrequently been mistaken for oesophageal stricture; or it may burst into the oesophagus, when fatal hemorrhage will occur. Compression or stretching of the sympathetic filaments

¹ Rev. de Méd., Paris, 1903.

may, in the former case, produce dilatation of the pupil; in the latter, contraction, if the conducting power is abolished, on the affected side. This has proved to be an important diagnostic sign in this disease. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist, or in the left superficial temporal artery; or the tumor may present itself at or above the manubrium, generally either in the median line, or to the right of the sternum, and may simulate an aneurism of one of the arteries of the neck.

Many of the physical signs of an aortic aneurism may be simulated with extraordinary fidelity by the preternatural pulsation or throbbing of a distended and elastic aorta, when no true aneurismal dilatation exists. This condition may be met with in young persons with aortic reflux and greatly hypertrophied hearts, in patients who are of a neurotic or hysterical temperament, and in cases of Graves' disease or of marked anemia. The condition is known as dynamic dilatation of the aorta, and in no way threatens life.

Branches (Figs. 583, 584).—The branches given off from the arch of the aorta are three in number: the **innominate**, the **left common carotid**, and the **left subclavian**.

Peculiarities.—*Position of the Branches.*—The branches, instead of arising from the highest part of the arch, may spring from the commencement of the arch or upper part of the ascending aorta; or the distance between them at their origins may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid toward the innominate artery.

The number of the primary branches may be reduced to one, or more commonly two; the left carotid arising from the innominate artery; or (more rarely) the carotid and subclavian arteries of the left side arising from a left innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it is the second or third branch given off, instead of the first. Another common form in which there are four primary branches is that in which the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks from the arch may be increased to five or six; in these instances, the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides. In some few cases six branches have been found, and this condition is associated with the origin of both vertebral arteries from the arch.

Number Usual, Arrangement Different.—When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual; the innominate artery is a left one, and the right carotid and subclavian arise separately. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

In some instances other arteries spring from the arch of the aorta. Of these the most common are the bronchial, one or both, and the thyroidea ima; but the internal mammary and the inferior thyroid have been seen to arise from this vessel.

The Innominate Artery (*A. Anonyma*; *Brachiocephalic Artery*) (Fig. 583).

The **innominate artery** is the largest branch of the arch of the aorta, and is from 4 to 5 cm. in length. It *arises*, on a level with the upper border of the second right costal cartilage, from the commencement of the arch of the aorta, on a plane anterior to the origin of the left carotid; it ascends obliquely upward, backward, and to the right to the level of the upper border of the right sternoclavicular articulation, where it divides into the right common carotid and right subclavian arteries.

Relations.—*Anteriorly*, it is separated from the manubrium sterni by the Sternohyoideus and Sternothyroideus, the remains of the thymus, the left innominate and right inferior thyroid veins which cross its root, and sometimes the superior cardiac branches of the right vagus. *Posterior* to it is the trachea, which it crosses obliquely. On the *right side* are the right innominate vein, the superior vena cava, the right phrenic nerve, and the pleura; and on the *left side*, the remains of the thymus, the origin of the left common carotid artery, the inferior thyroid veins, and the trachea.

Branches.—The innominate artery usually gives off no branches; but occasionally a small branch, the **thyroidea ima**, arises from it. Sometimes it gives off a **thymic** or **bronchial** branch.

The **thyreoidea ima** (*a. thyreoidea ima*) ascends in front of the trachea to the lower part of the thyroid gland, which it supplies. It varies greatly in size, and appears to compensate for deficiency or absence of one of the other thyroid vessels. It occasionally arises from the aorta, the right common carotid, the subclavian or the internal mammary.

Point of Division.—The innominate artery sometimes divides above the level of the sternoclavicular joint, less frequently below it.

Position.—When the aortic arch is on the right side, the innominate is directed to the left side of the neck.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligature of the innominate artery, by tying and dividing that artery. He then found that "Even coarse injection, impelled into the aorta, passed freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely."¹ The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while the anastomosis between the costocervical of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct course, into the right subclavian. The numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the inferior epigastric from the external iliac would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the chest.

Applied Anatomy.—Aneurism of the innominate artery not infrequently occurs as an accompaniment to aneurism of the arch of the aorta. It causes bulging of the right sternoclavicular articulation, pushing forward the Sternocleidomastoideus muscle and filling up the jugular notch. It produces serious pressure symptoms; from pressure on the innominate veins it may cause cedema of the upper extremities, and of the head and neck; from pressure on the trachea it produces dyspnoea; and from pressure on the right recurrent nerve, hoarseness and laryngeal cough.

Although the operation of tying the innominate artery has been performed by several surgeons, not many successes have been recorded. The chief danger of the operation appears to be the frequency of secondary hemorrhage; but in the present day, with the practice of aseptic surgery and our greater knowledge of the use of the ligature, more favorable results may be anticipated. The main obstacles to the operation are, the deep situation of the artery behind the sternum, and the number of important structures which surround it.

In order to apply a ligature to this vessel, the patient is to be placed upon his back with the thorax slightly raised, the head bent a little backward, and the right shoulder strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision 7 cm. or more in length is then made along the anterior border of the Sternocleidomastoideus, terminating at the sternal end of the clavicle. From this point, a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided; the sternal end of the Sternocleidomastoideus is now brought into view, and a director being passed beneath it, and close to its deep surface so as to avoid any small vessels, it is to be divided; in like manner the clavicular origin is to be divided throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear, the Sternohyoideus and Sternothyreoideus muscles will be exposed, and must be divided. The inferior thyroid veins may come into view, and must be carefully drawn either upward or downward, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibrocellular lamina, the right common carotid is brought into view, and being traced downward, the innominate artery is reached. The left innominate vein should now be depressed; the right innominate vein, the internal jugular vein, and the vagus nerve drawn to the right side; and a curved aneurism needle may then be passed around the vessel, close to its surface, and in a direction from below upward and medially; care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum. The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac while including the vessel in the ligature, should be most carefully borne in mind.

¹ Surgical Anatomy of the Head and Neck, p. 62.

THE ARTERIES OF THE HEAD AND NECK.

The principal arteries of supply to the head and neck are the two **common carotids**; they ascend in the neck and each divides into two branches, viz., (1) the **external carotid**, supplying the exterior of the head, the face, and the greater part of the neck; (2) the **internal carotid**, supplying to a great extent the parts within the cranial and orbital cavities.

THE COMMON CAROTID ARTERY (A. CAROTIS COMMUNIS).

The **common carotid arteries** differ in length and in their mode of origin. The *right* begins at the bifurcation of the innominate artery behind the sternoclavicular joint and is confined to the neck. The *left* springs from the highest part of the arch of the aorta to the left of, and on a plane posterior to the innominate artery, and therefore consists of a thoracic and a cervical portion.

The **thoracic portion of the left common carotid artery** ascends from the arch of the aorta through the superior mediastinal cavity to the level of the left sternoclavicular joint, where it is continuous with the cervical portion.

Relations.—*In front*, it is separated from the manubrium sterni by the Sternohyoideus and Sternothyroideus, the anterior portions of the left pleura and lung, the left innominate vein, and the remains of the thymus; *behind*, it lies on the trachea, cesophagus, left recurrent nerve, and thoracic duct. To its *right side* below is the innominate artery, and above, the trachea, the inferior thyroid veins, and the remains of the thymus; to its *left side* are the left vagus and phrenic nerves, left pleura, and lung. The left subclavian artery is posterior and slightly lateral to it.

The **cervical portions** of the common carotids resemble each other so closely that one description will apply to both (Fig. 585). Each vessel passes obliquely upward, from behind the sternoclavicular articulation, to the level of the upper border of the thyroid cartilage, where it divides into the external and internal carotid arteries.

At the lower part of the neck the two common carotid arteries are separated from each other by a very narrow interval which contains the trachea; but at the upper part, the thyroid gland, the larynx and pharynx project forward between the two vessels. The common carotid artery is contained in a sheath, which is derived from the deep cervical fascia and encloses also the internal jugular vein and vagus nerve, the vein lying lateral to the artery, and the nerve between the artery and vein, on a plane posterior to both. On opening the sheath, each of these three structures is seen to have a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very deeply seated, being *covered by* the integument, superficial fascia, Platysma, and deep cervical fascia, the Sternocleidomastoideus, Sternohyoideus, Sternothyroideus, and Omohyoideus; in the upper part of its course it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and medial margin of the Sternocleidomastoideus. When the latter muscle is drawn backward, the artery is seen to be contained in a triangular space, the **carotid triangle**, bounded behind by the Sternocleidomastoideus, above by the Stylohyoideus and posterior belly of the Digastricus, and below by the superior belly of the Omohyoideus. This part of the artery is crossed obliquely, from its medial to its lateral side, by the sternocleidomastoid branch of the superior thyroid artery; it is also crossed by the superior and middle thyroid veins which end in the internal jugular; descending in front of its sheath is the descending branch of the hypoglossal nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel obliquely. Sometimes the descending branch of the hypoglossal nerve is contained within the sheath. The superior thyroid vein crosses the artery near its termination, and the middle thyroid vein a little below the level of the cricoid cartilage; the anterior jugular vein crosses the artery just above the clavicle, but is separated from it by the Sternohyoideus and Sternothyroideus. *Behind*, the artery is separated from the transverse processes of the cervical vertebræ by the Longus colli and Longus capitis, the sympathetic trunk being interposed between it and the muscles. The inferior thyroid artery crosses behind the lower part of the vessel. *Medially*, it is in relation with the cesophagus, trachea, and thyroid gland (which overlaps it), the inferior thyroid artery and recurrent nerve being interposed; higher

up, with the larynx and pharynx. *Lateral* to the artery are the internal jugular vein and vagus nerve.

At the lower part of the neck, the right recurrent nerve crosses obliquely behind the artery; the right internal jugular vein diverges from the artery, but the left approaches and often overlaps the lower part of the artery.

Behind the angle of bifurcation of the common carotid artery is a reddish-brown oval body, known as the *glomus caroticum* (*carotid body*). It is similar in structure to the *glomus coccygeum* (*coccygeal body*) which is situated on the middle sacral artery.

FIG. 585.—Superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.

Peculiarities as to Origin. -The *right common carotid* may arise above the level of the upper border of the sternoclavicular articulation; this variation occurs in about 12 per cent. of cases. In other cases the artery may arise as a separate branch from the arch of the aorta, or in conjunction with the left carotid. The *left common carotid* varies in its origin more than the right. In the majority of abnormal cases it arises with the innominate artery; if that artery is absent, the two carotids arise usually by a single trunk. It is rarely joined with the left subclavian, except in cases of transposition of the aortic arch.

Peculiarities as to Point of Division. -In the majority of abnormal cases this occurs higher than usual, the artery dividing opposite or even above the hyoid bone; more rarely, it occurs

below, opposite the middle of the larynx, or the lower border of the cricoid cartilage; one case is related by Morgagni, where the artery was only 4 cm. in length and divided at the root of the neck. Very rarely, the common carotid ascends in the neck without any subdivision, either the external or the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

Occasional Branches.—The common carotid usually gives off no branch previous to its bifurcation, but it occasionally gives origin to the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or, more rarely, the vertebral artery.

Applied Anatomy.—Aneurisms are not commonly met with on the common carotid; when they do occur they are usually situated low down at the root of the neck, or just below the point of bifurcation of the vessel. They do not frequently assume a large size, and are more commonly found on the right side. As they increase in size they displace the trachea and larynx, and therefore dyspnoea becomes a prominent symptom. Dysphagia also may be present from pressure on the œsophagus, especially if the aneurism is on the left side; and pressure on the recurrent nerve may produce hoarseness and laryngeal cough. Pressure on the sympathetic will cause pupillary changes—dilatation of the pupil when the sympathetic is irritated, contraction when it has become paralyzed—and may also give rise to unilateral sweating. Pressure on the superficial branches of the cervical plexus may give rise to pain in the head, face, and neck; pressure on the vagus to irregular action of the heart and to asthmatic attacks. It is important to bear in mind that an enlarged lymph gland in the superior carotid triangle, receiving a transmitted pulsation from the carotid artery, may simulate aneurism of that vessel, but may be distinguished from it by the character of the pulsation, which is not distensible.

Embolism of the left common carotid has been known to produce aphasia by interference with the blood supply of the brain.

Digital compression of the common carotid is sometimes required, and is best effected by compressing the vessel with the thumb against the anterior tubercle of the transverse process of the sixth cervical vertebra (see p. 199).

Ligature of the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurism, or in a case of pulsating tumor of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery above and below the wounded part. In cases of aneurism, the whole of the artery is accessible, and any part of it may be tied. When the case is such as to allow of a choice being made, the upper part of the carotid should be selected as the spot upon which to place a ligature, for the lower part of the vessel is placed very deeply in the neck, and is covered by three layers of muscles; moreover, on the left side, the internal jugular vein, in the great majority of cases, passes obliquely in front of it. The part of the vessel which is most favorable for the operation is that opposite the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position; if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid, or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the diseased area.

In this operation, the direction of the vessel and the anterior margin of the Sternocleidomastoideus are the chief guides to its performance. The patient should be placed on his back with the head extended and turned slightly to the opposite side; an incision is to be made, 7 or 8 cm. long, in the direction of the anterior border of the Sternocleidomastoideus, so that the centre corresponds to the level of the cricoid cartilage. After dividing the integument, superficial fascia, Platysma, and deep fascia, the margins of the wound are held asunder by retractors, and the ramus descendens hypoglossi is now exposed, and must be avoided. The sheath of the vessel is to be raised by forceps, and opened to a small extent over the artery at its medial side. The internal jugular vein may present itself alternately distended and relaxed, and must be carefully avoided. The aneurism needle is passed from the lateral aspect, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein, or including the vagus nerve. Before the ligature is tied, it should be ascertained that nothing but the artery is included in it.

Ligature of the common carotid near the root of the neck is sometimes required in cases of aneurism of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sternocleidomastoideus, but may be done in some cases, if the aneurism is not of very large size, by an incision along the anterior border of the muscle, extending down to the sternoclavicular articulation, and by then retracting the muscle. The easiest and best plan, however, is to make an incision 5 to 7 cm. long down the lower part of the anterior border of the Sternocleidomastoideus to the sternoclavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about 5 cm. This incision is made through the superficial and deep fasciæ and the sternal origin of the muscle is exposed. This is to be divided on a director and turned up, with the superficial struc-

tures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the lateral border of the Sternohyoideus exposed. In doing this, care must be taken not to wound the anterior jugular vein, which crosses this muscle to reach the external jugular or subclavian vein. The Sternohyoideus and Sternothyroideus are to be drawn medialward by means of a retractor, and the sheath of the vessel exposed. This must be opened on its medial or tracheal side, so as to avoid the internal jugular vein. Special care is necessary on the left side, where the artery is commonly overlapped by the vein; on the right side there is usually an interval between the artery and the vein, and the risk of wounding the latter is less.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasdor's operation for the cure of an aneurism of the lower part of the vessel. Brasdor's procedure consists in ligaturing the artery on the distal side of the aneurism, and in the case of the common carotid there are no branches given off from the vessel between the aneurism and the site of the ligature; hence the flow of blood through the sac of the aneurism is diminished, and cure takes place in the usual way by the deposit of laminated fibrin.

Collateral Circulation.—After ligature of the common carotid, the collateral circulation can be perfectly established, by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied. The chief communications outside the skull take place between the superior and inferior thyroid arteries, and the profunda cervicis and ramus descendens of the occipital; the vertebral takes the place of the internal carotid within the cranium.

The External Carotid Artery (*A. Carotis Externa*) (Fig. 585).

The external carotid artery begins opposite the upper border of the thyroid cartilage, and, taking a slightly curved course, passes upward and forward, and then inclines backward to the space behind the neck of the mandible, where it divides into the superficial temporal and internal maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of the branches given off from it. In the child, it is somewhat smaller than the internal carotid; but in the adult, the two vessels are of nearly equal size. At its origin, this artery is more superficial, and placed nearer the middle line than the internal carotid, and is contained within the carotid triangle.

Relations.—The external carotid artery is covered by the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sternocleidomastoideus; it is crossed by the hypoglossal nerve, by the lingual, ranine, common facial, and superior thyroid veins; and by the Digastricus and Stylohyoideus; higher up it passes deeply into the substance of the parotid gland, where it lies deep to the facial nerve and the junction of the temporal and internal maxillary veins. Medial to it are the hyoid bone, the wall of the pharynx, the superior laryngeal nerve, and a portion of the parotid gland. Lateral to it, in the lower part of its course, is the internal carotid artery. Posterior to it, near its origin, is the superior laryngeal nerve; and higher up, it is separated from the internal carotid by the Styloglossus and Stylopharyngeus, the glossopharyngeal nerve, the pharyngeal branch of the vagus, and part of the parotid gland.

Applied Anatomy.—Ligature of the external carotid may be required in cases of wound of this vessel or of its branches when these cannot be tied, and in some cases of pulsating tumors of the scalp or face. It is also done as a preliminary measure to excision of the maxilla. The seat of election for ligature is between the origins of its superior thyroid and lingual branches, about a finger's breadth below the tip of the greater cornu of the hyoid bone. To tie the vessel, an incision is made from the angle of the mandible to the upper border of the thyroid cartilage, and the superficial tissues and the deep fascia divided. The anterior border of the Sternocleidomastoideus must be retracted and the lower border of the parotid gland raised, so as to expose the tendon of the Digastricus and the hypoglossal nerve, which cross the artery. The great difficulty in doing this is due to the plexus of veins derived from the superior thyroid and lingual veins, which overlie the artery. If necessary, these must be ligatured and divided. Care must be taken not to mistake the lingual and external maxillary, when they arise by a common trunk, as they sometimes do, for the external carotid. The needle is to be passed from the lateral to the medial side of the vessel, carefully avoiding the superior laryngeal nerve, which lies in close proximity to the artery. The circulation is at once reestablished by the free communication between most of the large branches of the artery (external maxillary, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid, and of the occipital with branches of the subclavian, etc.

Branches. The branches of the external carotid artery may be divided into four sets.

<i>Anterior.</i>	<i>Posterior.</i>	<i>Ascending.</i>	<i>Terminal.</i>
Superior Thyroid.	Occipital.	Ascending	Superficial Temporal.
Lingual.	Posterior Auricular.	Pharyngeal.	Internal Maxillary.
External Maxillary.			

1. The **superior thyroid artery** (*a. thyreoidea superior*) (Fig. 585) *arises* from the external carotid artery just below the level of the greater cornu of the hyoid bone and ends in the thyroid gland.

Relations.—From its origin under the anterior border of the Sternocleidomastoideus it runs upward and forward for a short distance in the carotid triangle, where it is covered by the skin, Platysma, and fascia; it then arches downward beneath the Omohyoideus, Sternohyoideus, and Sternothyreoideus. To its medial side are the Constrictor pharyngis inferior and the external branch of the superior laryngeal nerve.

Branches.—It distributes twigs to the adjacent muscles, and numerous branches to the thyroid gland, anastomosing with its fellow of the opposite side, and with the inferior thyroid arteries. The branches to the gland are generally two in number; one, the larger, supplies principally the anterior surface; on the isthmus of the gland it anastomoses with the corresponding artery of the opposite side: a second branch descends on the posterior surface of the gland and anastomoses with the inferior thyroid artery.

Besides the arteries distributed to the muscles and to the thyroid gland, the branches of the superior thyroid are:

Hyoid.	Superior Laryngeal.
Sternocleidomastoid.	Cricothyroid.

The **Hyoid Branch** (*ramus hyoideus; infrahyoid branch*) is small and runs along the lower border of the hyoid bone beneath the Thyreohyoideus and anastomoses with the vessel of the opposite side.

The **Sternocleidomastoid Branch** (*ramus sternocleidomastoideus; sternomastoid branch*) runs downward and lateralward across the sheath of the common carotid artery, and supplies the Sternocleidomastoideus and neighboring muscles and integument; it frequently *arises* as a separate branch from the external carotid.

The **Superior Laryngeal Artery** (*a. laryngea superior*), larger than either of the preceding, accompanies the internal laryngeal branch of the superior laryngeal nerve, beneath the Thyreohyoideus; it pierces the hyothyroid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **Cricothyroid Branch** (*ramus cricothyreoideus*) is small and runs transversely across the cricothyroid membrane, communicating with the artery of the opposite side.

Applied Anatomy.—The superior thyroid, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hemorrhage. In such cases, the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the artery being very superficial, and the only structures of importance covering it being a few small veins. The operation of tying the superior thyroid artery in bronchocele has been performed, but the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is so free that the operation has been given up, especially as better results are obtained by other means.

The position of the sternocleidomastoid branch is of importance in connection with the operation of ligature of the common carotid artery. It crosses and lies on the sheath of this vessel and may chance to be wounded in opening the sheath. The position of the cricothyroid branch should be remembered, as it may prove the source of troublesome hemorrhage during the operation of laryngotomy.

2. The **lingual artery** (*a. lingualis*) (Fig. 590) *arises* from the external carotid between the superior thyroid and external maxillary; it first runs obliquely upward and medialward to the greater cornu of the hyoid bone; it then curves downward

and forward, forming a loop which is crossed by the hypoglossal nerve, and passing beneath the Digastricus and Stylohyoideus it runs horizontally forward, beneath the Hyoglossus, and finally, ascending almost perpendicularly to the tongue, turns forward on its lower surface as far as the tip, under the name of the *profunda linguae*.

Relations.—Its first, or oblique, portion is superficial, and is contained within the carotid triangle; it rests upon the Constrictor pharyngis medius, and is covered by the Platysma and the fascia of the neck. Its second, or curved, portion also lies upon the Constrictor pharyngis medius, being covered at first by the tendon of the Digastricus and by the Stylohyoideus, and afterward by the Hyoglossus. Its third, or horizontal, portion lies between the Hyoglossus and Genioglossus. The fourth, or terminal part, under the name of the *profunda linguae* (*ranine artery*) runs along the under surface of the tongue to its tip; here it is superficial, being covered only by the mucous membrane; above it is the Longitudinalis inferior, and on the medial side the Genioglossus. The hypoglossal nerve crosses the first part of the lingual artery, but is separated from the second part by the Hyoglossus.

Branches.—The branches of the lingual artery are:

Hyoid.	Sublingual.
Dorsales linguae.	Profunda linguae.

The **Hyoid Branch** (*ramus hyoideus; suprahyoid branch*) runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The **Arteriae Dorsales Linguae** (*rami dorsales linguae*) consist usually of two or three small branches which arise beneath the Hyoglossus; they ascend to the back part of the dorsum of the tongue, and supply the mucous membrane in this situation, the glossopalatine arch, the tonsil, soft palate, and epiglottis; anastomosing with the vessels of the opposite side.

The **Sublingual Artery** (*a. sublingualis*) arises at the anterior margin of the Hyoglossus, and runs forward between the Genioglossus and Mylohyoideus to the sublingual gland. It supplies the gland and gives branches to the Mylohyoideus and neighboring muscles, and to the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the mandible in the substance of the gum to anastomose with a similar artery from the other side; another pierces the Mylohyoideus and anastomoses with the submental branch of the external maxillary artery.

The **Arteria Profunda Linguae** (*ranine artery; deep lingual artery*) is the terminal portion of the lingual artery; it pursues a tortuous course and runs along the under surface of the tongue, below the Longitudinalis inferior, and above the mucous membrane; it lies on the lateral side of the Genioglossus, accompanied by the lingual nerve. At the tip of the tongue, it is said to anastomose with the artery of the opposite side, but this is denied by Hyrtl. In the mouth, these vessels are placed one on either side of the frenulum linguae.

Applied Anatomy.—The lingual artery is not infrequently divided near its origin in cases of cut throat; while severe hemorrhage, which cannot be restrained by ordinary means, may ensue from a wound, or deep ulcer, of the tongue. In the former case, the primary wound may be enlarged if necessary, and the bleeding vessel secured; in the latter, it has been suggested that the lingual artery should be tied near its origin. Ligature of the lingual artery has been also occasionally practised, as a preliminary measure to removal of the tongue. The operation is a difficult one on account of the depth of the artery, the number of important parts by which it is surrounded, and its occasional irregularity of origin. An incision is to be made in a curved direction from a finger's breadth behind the symphysis menti downward to the cornu of the hyoid bone, and then upward to near the angle of the mandible. Care must be taken not to carry this incision too far backward, for fear of endangering the anterior facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia displayed. This is then to be incised and the submaxillary gland exposed and pulled upward by retractors. A triangular space is now seen, bounded in front by the posterior border of the Mylohyoideus; below and behind, by the tendon of the Digastricus; and above, by the hypoglossal nerve. The floor of the space is formed by the Hyoglossus, beneath which the artery lies. The parts are to

be drawn forward by a blunt hook inserted beneath the tendon of the Digastricus, and the fibres of the Hyoglossus cut through horizontally just above the Digastricus. The artery will then be exposed; and in passing the aneurism needle, care must be taken not to open the pharynx. The hypoglossal nerve must also be avoided.

Troublesome hemorrhage may occur in the division of the frenulum linguae in children, if the aa. profundae linguae, which lie one on either side of it, be wounded. The operation should always be performed with a pair of blunt-pointed scissors, and the mucous membrane alone divided by a very superficial cut, which cannot endanger any vessel. Any further liberation of the tongue which may be necessary can be effected by tearing.

FIG. 586.—The arteries of the face and scalp.¹

3. The **external maxillary artery** (*a. maxillaris externa*; *facial artery*) (Fig. 586), *arises* in the carotid triangle a little above the lingual artery and, sheltered by the ramus of the mandible, passes obliquely up beneath the Digastricus and Stylohyoideus, over which it arches to enter a groove on the posterior surface of the submaxillary gland. It then curves upward over the body of the mandible at the antero-inferior angle of the Masseter; passes forward and upward across the cheek to the angle of the mouth, then ascends along the side of the nose, and ends at the medial commissure of the eye, under the name of the **angular artery**. This vessel, both in the neck and on the face, is remarkably tortuous: in the former situation, to accommodate itself to the movements of the pharynx in deglutition; and in the latter, to the movements of the mandible, lips, and cheeks.

Relations.—*In the neck*, its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastricus and Stylohyoideus muscles and part of the

¹ The muscular tissue of the lips must be supposed to have been cut away, in order to show the course of the labial arteries.

submaxillary gland, and frequently beneath the hypoglossal nerve. It lies upon the Constrictores pharyngis medius and superior, the latter of which separates it, at the summit of its arch, from the lower and back part of the tonsil. *On the face*, where it passes over the body of the mandible, it is comparatively superficial, lying immediately beneath the Platysma. In its course over the face, it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomaticus. It rests on the Buccinator and Caninus, and passes either over or under the infraorbital head of the Quadratus labii superioris. The anterior facial vein lies lateral to the artery, and takes a more direct course across the face, where it is separated from the artery by a considerable interval. In the neck it lies superficial to the artery. The branches of the facial nerve cross the artery from behind forward.

Branches.—The branches of the artery may be divided into two sets: those given off in the neck (*cervical*), and those on the face (*facial*).

Cervical Branches.

Ascending Palatine.
Tonsillar.
Glandular.
Submental.
Muscular.

Facial Branches.

Inferior Labial.
Superior Labial.
Lateral Nasal.
Angular.
Muscular.

The **Ascending Palatine Artery** (*a. palatina ascendens*) (Fig. 590) arises close to the origin of the external maxillary artery and passes up between the Styloglossus and Stylopharyngeus to the side of the pharynx, along which it is continued between the Constrictor pharyngis superior and the Pterygoideus internus to near the base of the skull. It divides near the Levator veli palatini into two branches: one follows the course of this muscle, and, winding over the upper border of the Constrictor pharyngis superior, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the descending palatine branch of the internal maxillary artery; the other pierces the Constrictor pharyngis superior and supplies the palatine tonsil and auditory tube, anastomosing with the tonsillar and ascending pharyngeal arteries.

The **Tonsillar Branch** (*ramus tonsillaris*) (Fig. 590) ascends between the Pterygoideus internus and Styloglossus, and then along the side of the pharynx, perforating the Constrictor pharyngis superior, to ramify in the substance of the palatine tonsil and root of the tongue.

The **Glandular Branches** (*rami glandulares; submaxillary branches*) consist of three or four large vessels, which supply the submaxillary gland, some being prolonged to the neighboring muscles, lymph glands, and integument.

The **Submental Artery** (*a. submentalis*) the largest of the cervical branches, is given off from the facial artery just as that vessel quits the submaxillary gland: it runs forward upon the Mylohyoideus, just below the body of the mandible, and beneath the Digastricus. It supplies the surrounding muscles, and anastomoses with the sublingual artery and with the mylohyoid branch of the inferior alveolar; at the symphysis menti it turns upward over the border of the mandible and divides into a superficial and a deep branch. The superficial branch passes between the integument and Quadratus labii inferioris, and anastomoses with the inferior labial artery; the deep branch runs between the muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **Inferior Labial Artery** (*a. labialis inferior; inferior coronary artery*) arises near the angle of the mouth; it passes upward and forward beneath the Triangularis and, penetrating the Orbicularis oris, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane. It supplies the labial glands, the mucous membrane, and the muscles of the lower lip; and anastomoses with the artery of the opposite side, and with the mental branch of the inferior alveolar artery.

The **Superior Labial Artery** (*a. labialis superior; superior coronary artery*) is larger and more tortuous than the inferior. It follows a similar course along the edge

of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the upper lip, and gives off in its course two or three vessels which ascend to the nose; a **septal branch** ramifies on the nasal septum as far as the point of the nose, and an **alar branch** supplies the ala of the nose.

The **Lateral Nasal branch** is derived from the external maxillary as that vessel ascends along the side of the nose. It supplies the ala and dorsum of the nose, anastomosing with its fellow, with the septal and alar branches, with the dorsal nasal branch of the ophthalmic, and with the infraorbital branch of the internal maxillary.

The **Angular Artery** (*a. angularis*) is the terminal part of the external maxillary; it ascends to the medial angle of the orbit, imbedded in the fibres of the angular head of the Quadratus labii superioris, and accompanied by the angular vein. On the cheek it distributes branches which anastomose with the infraorbital; after supplying the lacrimal sac and Orbicularis oculi, it ends by anastomosing with the dorsal nasal branch of the ophthalmic artery.

The **Muscular Branches** in the neck are distributed to the Pterygoideus internus and Stylohyoideus, and on the face to the Masseter and Buccinator. The anastomoses of the external maxillary artery are very numerous, not only with the vessel of the opposite side, but, *in the neck*, with the sublingual branch of the lingual, with the ascending pharyngeal, and by its ascending palatine and tonsillar branches with the palatine branch of the internal maxillary; *on the face*, with the mental branch of the inferior alveolar as it emerges from the mental foramen, with the transverse facial branch of the superficial temporal, with the infraorbital branch of the internal maxillary, and with the dorsal nasal branch of the ophthalmic.

Peculiarities.—The external maxillary artery not infrequently arises in common with the lingual. It varies in its size and in the extent to which it supplies the face; it occasionally ends as the submental, and not infrequently extends only as high as the angle of the mouth or nose. The deficiency is then compensated for by enlargement of one of the neighboring arteries.

Applied Anatomy.—The passage of the external maxillary artery over the body of the mandible would appear to afford a favorable position for the application of pressure in cases of hemorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow, and with numerous branches from different sources. In a wound involving the lip, it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure forceps. In order to prevent hemorrhage in cases of removal of growths from the lip, the latter should be compressed on either side between the fingers and thumb, or by a pair of specially devised clamp forceps, while the surgeon excises the diseased part. In order to stop hemorrhage when the lip has been divided in an operation, it is necessary, when closing the wound, to pass the sutures through the cut edges, almost as deep as its mucous surface; by these means, not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hemorrhage is prevented by including the divided artery in the suture. If, on the contrary, the suture be passed through merely the cutaneous portion of the wound, hemorrhage occurs into the cavity of the mouth. The student should observe the relation of the angular artery to the lacrimal sac; as the vessel passes up along the medial margin of the orbit, it ascends on the nasal side of the sac. In operating for fistula lacrimalis, the sac should always be opened on its lateral side in order that this vessel may be avoided.

4. The **occipital artery** (*a. occipitalis*) (Fig. 586) arises from the posterior part of the external carotid, opposite the external maxillary, near the lower margin of the posterior belly of the Digastricus, and ends in the posterior part of the scalp.

Course and Relations.—At its origin, it is covered by the posterior belly of the Digastricus and the Stylohyoideus, and the hypoglossal nerve winds around it from behind forward; higher up, it crosses the internal carotid artery, the internal jugular vein, and the vagus and accessory nerves. It next ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backward, grooving the surface of the latter bone, being covered by the Sternocleidomastoideus, Splenius capitis, Longissimus capitis, and Digastricus, and resting upon the Rectus capitis lateralis, the Obliquus superior, and Semispinalis capitis. It then changes its course and runs vertically upward, pierces the fascia connecting the cranial attachment of the Trapezius with the Sternocleidomastoideus, and ascends

in a tortuous course in the superficial fascia of the scalp, where it divides into numerous branches, which reach as high as the vertex of the skull and anastomose with the posterior auricular and superficial temporal arteries. Its terminal portion is accompanied by the greater occipital nerve.

Branches.—The branches of the occipital artery are:

Muscular.	Sternocleidomastoid.	Auricular.
Meningeal.	Descending.	

The **Muscular Branches** (*rami musculares*) supply the Digastricus, Stylohyoideus, Splenius, and Longissimus capitis.

The **Sternocleidomastoid Artery** (*a. sternocleidomastoidea; sternomastoid artery*) generally arises from the occipital close to its commencement, but sometimes springs directly from the external carotid. It passes downward and backward over the hypoglossal nerve, and enters the substance of the muscle, in company with the accessory nerve.

The **Auricular Branch** (*ramus auricularis*) supplies the back of the concha and frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura mater, the diploë, and the mastoid cells; this latter branch sometimes arises from the occipital artery, and is then known as the **mastoid branch**.

The **Meningeal Branch** (*ramus meningeus; dural branch*) ascends with the internal jugular vein, and enters the skull through the jugular foramen and condyloid canal, to supply the dura mater in the posterior fossa.

The **Descending Branch** (*ramus descendens; arteria princeps cervicis*) (Fig. 590), the largest branch of the occipital, descends on the back of the neck, and divides into a superficial and deep portion. The superficial portion runs beneath the Splenius, giving off branches which pierce that muscle to supply the Trapezius and anastomose with the ascending branch of the transverse cervical: the deep portion runs down between the Semispinales capitis and colli, and anastomoses with the vertebral and with the *a. profunda cervicalis*, a branch of the costocervical trunk. The anastomosis between these vessels assists in establishing the collateral circulation after ligature of the common carotid or subclavian artery.

The terminal branches of the occipital artery are distributed to the back of the head: they are very tortuous, and lie between the integument and Occipitalis, anastomosing with the artery of the opposite side and with the posterior auricular and temporal arteries, and supplying the Occipitalis, the integument, and pericranium. One of the terminal branches may give off a meningeal twig which passes through the parietal foramen.

5. The **posterior auricular artery** (*a. auricularis posterior*) (Fig. 586) is small and arises from the external carotid, above the Digastricus and Stylohyoideus, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into its auricular and occipital branches.

Branches.—Besides several small branches to the Digastricus, Stylohyoideus, and Sternocleidomastoideus, and to the parotid gland, this vessel gives off three branches:

Stylomastoid.	Auricular.	Occipital.
---------------	------------	------------

The **Stylomastoid Artery** (*a. stylomastoidea*) enters the stylomastoid foramen and supplies the tympanic cavity, the tympanic antrum and mastoid cells, and the semicircular canals. In the young subject a branch from this vessel forms, with the anterior tympanic artery from the internal maxillary, a vascular circle, which surrounds the tympanic membrane, and from which delicate vessels ramify on that membrane. It anastomoses with the superficial petrosal branch of the middle meningeal artery by a twig which enters the hiatus canalis facialis.

The **Auricular Branch** (*ramus auricularis*) ascends behind the ear, beneath the Auricularis posterior, and is distributed to the back of the auricle, upon which it ramifies minutely, some branches curving around the margin of the cartilage, others perforating it, to supply the anterior surface. It anastomoses with the parietal and anterior auricular branches of the superficial temporal.

The **Occipital Branch** (*ramus occipitalis*) passes backward, over the Sternocleidomastoideus, to the scalp above and behind the ear. It supplies the Occipitalis and the scalp in this situation and anastomoses with the occipital artery.

6. The **ascending pharyngeal artery** (*a. pharyngea ascendens*) (Fig. 590), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and under the Stylopharyngeus. It arises from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Longus capitis.

Branches.—Its branches are:

Pharyngeal.
Palatine.

Prevertebral.
Inferior Tympanic.

Posterior Meningeal.

The **Pharyngeal Branches** (*rami pharyngei*) are three or four in number. Two of these descend to supply the Constrictores pharyngis medius and inferior and the Stylopharyngeus, ramifying in their substance and in the mucous membrane lining them.

The **Palatine Branch** varies in size, and may take the place of the ascending palatine branch of the facial artery, when that vessel is small. It passes inward upon the Constrictor pharyngis superior, sends ramifications to the soft palate and tonsil, and supplies a branch to the auditory tube.

The **Prevertebral Branches** are numerous small vessels, which supply the Longi capitis and colli, the sympathetic trunk, the hypoglossal and vagus nerves, and the lymph glands; they anastomose with the ascending cervical artery.

The **Inferior Tympanic Artery** (*a. tympanica inferior*) is a small branch which passes through a minute foramen in the petrous portion of the temporal bone, in company with the tympanic branch of the glossopharyngeal nerve, to supply the medial wall of the tympanic cavity and anastomose with the other tympanic arteries.

The **Meningeal Branches** are several small vessels, which supply the dura mater. One, the **posterior meningeal**, enters the cranium through the jugular foramen; a second passes through the foramen lacerum; and occasionally a third through the canal for the hypoglossal nerve.

Applied Anatomy.—The ascending pharyngeal artery has been wounded from the throat; as in the case in which the stem of a tobacco pipe was driven into the vessel, causing fatal hemorrhage.

7. The **superficial temporal artery** (*a. temporalis superficialis*) (Fig. 586), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It begins in the substance of the parotid gland, behind the neck of the mandible, and crosses over the posterior root of the zygomatic process of the temporal bone; about 5 cm. above this process it divides into two branches, a frontal and a parietal.

Relations.—As it crosses the zygomatic process, it is covered by the Auricularis anterior muscle, and by a dense fascia; it is crossed by the temporal and zygomatic branches of the facial nerve and one or two veins, and is accompanied by the auriculotemporal nerve, which lies immediately behind it.

Branches.—Besides some twigs to the parotid gland, to the temporomandibular joint, and to the Masseter muscle, its branches are:

Transverse Facial.
Middle Temporal.

Anterior Auricular.
Frontal.

Parietal.

The **Transverse Facial Artery** (*a. transversa faciei*) is given off from the superficial temporal before that vessel quits the parotid gland; running forward through the substance of the gland, it passes transversely across the side of the face, between the parotid duct and the lower border of the zygomatic arch, and divides into numerous branches, which supply the parotid gland and duct, the Masseter, and the integument, and anastomose with the external maxillary, masseteric, buccinator, and infraorbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve.

The **Middle Temporal Artery** (*a. temporalis media*) arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the Temporalis, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off a **zygomatooörbital branch**, which runs along the upper border of the zygomatic arch, between the two layers of the temporal fascia, to the lateral angle of the orbit. This branch, which may arise directly from the superficial temporal artery, supplies the Orbicularis oculi, and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery.

The **Anterior Auricular Branches** (*rami auriculares anteriores*) are distributed to the anterior portion of the auricula, the lobule, and part of the external meatus, anastomosing with the posterior auricular.

The **Frontal Branch** (*ramus frontalis; anterior temporal*) runs tortuously upward and forward to the forehead, supplying the muscles, integument, and pericranium in this region, and anastomosing with the supraorbital and frontal arteries.

The **Parietal Branch** (*ramus parietalis; posterior temporal*) larger than the frontal, curves upward and backward on the side of the head, lying superficial to the temporal fascia, and anastomosing with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

Applied Anatomy.—The temporal artery, as it crosses the zygomatic process, lies immediately beneath the skin, and its pulsations may be readily felt during the administration of an anesthetic, or under circumstances where the radial pulse is not available; it may be easily compressed against the bone in order to check bleeding from the temporal region of the scalp. When a flap is raised from this part of the head, for trephining, the incision should be shaped like a horseshoe, with its convexity upward, so that the flap shall contain the temporal artery, which ensures a sufficient supply of blood. The same principle is applied, as far as possible, in making incisions to raise flaps in other parts of the scalp. Formerly the operation of arteriotomy was performed upon this vessel in cases of inflammation of the eye or brain, but this operation is now obsolete.

8. The **internal maxillary artery** (*a. maxillaris interna*) (Fig. 587), the larger of the two terminal branches of the external carotid, *arises* behind the neck of the mandible, and is at first imbedded in the substance of the parotid gland; it passes forward between the ramus of the mandible and the sphenomandibular ligament, and then runs, either superficial or deep to the Pterygoideus externus, to the pterygopalatine fossa. It supplies the deep structures of the face, and may be divided into **mandibular, pterygoid, and pterygopalatine portions**.

The **first or mandibular portion** passes horizontally forward, between the ramus of the mandible and the sphenomandibular ligament, where it lies parallel to and a little below the auriculotemporal nerve; it crosses the inferior alveolar nerve, and runs along the lower border of the Pterygoideus externus.

The **second or pterygoid portion** runs obliquely forward and upward under cover of the ramus of the mandible and insertion of the Temporalis, on the superficial (very frequently on the deep) surface of the Pterygoideus externus; it then passes between the two heads of origin of this muscle and enters the fossa.

The **third or pterygopalatine portion** lies in the pterygopalatine fossa in relation with the sphenopalatine ganglion.

The branches of this vessel may be divided into three groups (Fig. 588), corresponding with its three divisions.

branch

FIG. 587.—The internal maxillary artery.

FIG. 588.—Plan of branches of internal maxillary artery.

Branches of the First or Mandibular Portions.—

Anterior Tympanic.
Deep Auricular.

Middle Meningeal.
Accessory Meningeal.
Inferior Alveolar.

The **Anterior Tympanic Artery** (*a. tympanica anterior*; *tympanic artery*) passes upward behind the temporomandibular articulation, enters the tympanic cavity through the petrotympanic fissure, and ramifies upon the tympanic membrane, forming a vascular circle around the membrane with the stylomastoid branch of the posterior auricular, and anastomosing with the artery of the pterygoid canal and with the caroticotympanic branch from the internal carotid.

The **Deep Auricular Artery** (*a. auricularis profunda*) often arises in common with the preceding. It ascends in the substance of the parotid gland, behind the temporomandibular articulation, pierces the cartilaginous or bony wall of the external acoustic meatus, and supplies its cuticular lining and the outer surface of the tympanic membrane. It gives a branch to the temporomandibular joint.

• The **Middle Meningeal Artery** (*a. meningea media*; *medidural artery*) is the largest of the arteries which supply the dura mater. It ascends between the sphenomandibular ligament and the Pterygoideus externus, and between the two roots of the auriculotemporal nerve to the foramen spinosum of the sphenoid bone, through which it enters the cranium; it then runs forward in a groove on the great wing of the sphenoid bone, and divides into two branches, anterior and posterior. The **anterior branch**, the larger, crosses the great wing of the sphenoid, reaches the groove, or canal, in the sphenoidal angle of the parietal bone, and then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upward as far as the vertex, and others backward to the occipital region. The **posterior branch** curves backward on the squama of the temporal bone, and, reaching the parietal some distance in front of its mastoid angle, divides into branches which supply the posterior part of the dura mater and cranium. The branches of the middle meningeal artery are distributed partly to the dura mater, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal.

The middle meningeal on entering the cranium gives off the following branches: (1) Numerous small vessels supply the semilunar ganglion and the dura mater in this situation. (2) A **superficial petrosal branch** enters the hiatus of the facial canal, supplies the facial nerve, and anastomoses with the stylomastoid branch of the posterior auricular artery. (3) A **superior tympanic artery** runs in the canal for the Tensor tympani, and supplies this muscle and the lining membrane of the canal. (4) **Orbital branches** pass through the superior orbital fissure or through separate canals in the great wing of the sphenoid, to anastomose with the lacrimal or other branches of the ophthalmic artery. (5) **Temporal branches** pass through foramina in the great wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

Applied Anatomy.—The middle meningeal is an artery of considerable surgical importance, as it may be torn in fractures of the temporal region of the skull, or, indeed, by injuries causing separation of the dura mater from the bone, without fracture. The injury may be followed by considerable hemorrhage between the bone and dura mater, which produces symptoms of compression of the brain, and requires trephining for its relief. As the compression implicates the motor region of the cortex, paralysis on the opposite side of the body forms the prominent symptom of the lesion. The anterior branch of this artery crosses the sphenoidal angle of the parietal bone at a point 4 cm. behind the zygomatic process of the frontal bone, and 4.5 cm. above the zygomatic arch. From this point it passes upward and slightly backward to the sagittal suture, lying about 1.25 to 2 cm. behind the coronal suture. The posterior branch runs backward over the squama of the temporal bone. In order to expose the anterior branch of the artery, a point is taken 4 cm. above the zygomatic arch and the same distance behind the zygomatic process of the frontal bone. Here the pin of the trephine is to be applied. A horseshoe-shaped flap, measuring 8 cm. in length and transversely, and consisting of all the structures of the scalp down to and including the pericranium, is first made, with its base just above the zygomatic arch. This flap is reflected and a 2.5 cm. trephine applied. After the crown of bone has been removed, the blood clot is exposed, and gently got rid of, and if possible the bleeding-point must be found and controlled.

The **Accessory Meningeal Branch** (*ramus meningeus accessorius*; *small meningeal or parietal branch*) is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the semilunar ganglion and dura mater.

The **Inferior Alveolar Artery** (*a. alveolaris inferior; inferior dental artery*) descends with the inferior alveolar nerve to the mandibular foramen on the medial surface of the ramus of the mandible. It runs along the mandibular canal in the substance of the bone, accompanied by the nerve, and opposite the first premolar tooth divides into two branches, incisor and mental. The **incisor branch** is continued forward beneath the incisor teeth as far as the middle line, where it anastomoses with the artery of the opposite side; the **mental branch** escapes with the nerve at the mental foramen, supplies the chin, and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a **lingual branch** which descends with the lingual nerve and supplies the mucous membrane of the mouth. As the inferior alveolar artery enters the foramen, it gives off a **mylohyoid branch** which runs in the mylohyoid groove, and ramifies on the under surface of the Mylohyoideus. The inferior alveolar artery and its incisor branch during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the roots, and supply the pulp of the teeth.

Branches of the Second or Pterygoid Portion.—

Deep Temporal.
Pterygoid.

Masseteric.
Buccinator.

The **Deep Temporal Branches**, two in number, **anterior** and **posterior**, ascend between the Temporalis and the pericranium; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and great wing of the sphenoid.

The **Pterygoid Branches** (*rami pterygoidei*), irregular in their number and origin, supply the Pterygoidei.

The **Masseteric Artery** (*a. masseterica*) is small and passes lateralward through the mandibular notch to the deep surface of the Masseter. It supplies the muscle, and anastomoses with the masseteric branches of the external maxillary and with the transverse facial artery.

The **Buccinator Artery** (*a. buccinatoria; buccal artery*) is small and runs obliquely forward, between the Pterygoideus internus and the insertion of the Temporalis, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the external maxillary and with the infraorbital.

Branches of the Third or Pterygopalatine Portion.—

Posterior Superior Alveolar.
Infraorbital.
Descending Palatine.

Artery of the Pterygoid Canal.
Pharyngeal.
Sphenopalatine.

The **Posterior Superior Alveolar Artery** (*a. alveolaris superior posterior; alveolar or posterior dental artery*) is given off from the internal maxillary, frequently in conjunction with the infraorbital just as the trunk of the vessel is passing into the pterygopalatine fossa. Descending upon the tuberosity of the maxilla, it divides into numerous branches, some of which enter the alveolar canals, to supply the molar and premolar teeth and the lining of the maxillary sinus, while others are continued forward on the alveolar process to supply the gums.

The **Infraorbital Artery** (*a. infraorbitalis*) appears, from its direction, to be the continuation of the trunk of the internal maxillary, but often *arises* in conjunction with the posterior superior alveolar. It runs along the infraorbital groove and canal with the infraorbital nerve, and emerges on the face through the infraorbital foramen, beneath the infraorbital head of the Quadratus labii superioris. While in the canal, it gives off (*a*) **orbital branches** which assist in supplying the Rectus inferior and Obliquus inferior and the lacrimal sac, and (*b*) **anterior superior alveolar**

The **Anterior Tympanic Artery** (*a. tympanica anterior; tympanic artery*) passes upward behind the temporomandibular articulation, enters the tympanic cavity through the petrotympanic fissure, and ramifies upon the tympanic membrane, forming a vascular circle around the membrane with the stylomastoid branch of the posterior auricular, and anastomosing with the artery of the pterygoid canal and with the caroticotympanic branch from the internal carotid.

The **Deep Auricular Artery** (*a. auricularis profunda*) often arises in common with the preceding. It ascends in the substance of the parotid gland, behind the temporomandibular articulation, pierces the cartilaginous or bony wall of the external acoustic meatus, and supplies its cuticular lining and the outer surface of the tympanic membrane. It gives a branch to the temporomandibular joint.

• The **Middle Meningeal Artery** (*a. meningea media; medidural artery*) is the largest of the arteries which supply the dura mater. It ascends between the sphenomandibular ligament and the Pterygoideus externus, and between the two roots of the auriculotemporal nerve to the foramen spinosum of the sphenoid bone, through which it enters the cranium; it then runs forward in a groove on the great wing of the sphenoid bone, and divides into two branches, anterior and posterior. The **anterior branch**, the larger, crosses the great wing of the sphenoid, reaches the groove, or canal, in the sphenoidal angle of the parietal bone, and then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upward as far as the vertex, and others backward to the occipital region. The **posterior branch** curves backward on the squama of the temporal bone, and, reaching the parietal some distance in front of its mastoid angle, divides into branches which supply the posterior part of the dura mater and cranium. The branches of the middle meningeal artery are distributed partly to the dura mater, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal.

The middle meningeal on entering the cranium gives off the following branches: (1) Numerous small vessels supply the semilunar ganglion and the dura mater in this situation. (2) A **superficial petrosal branch** enters the hiatus of the facial canal, supplies the facial nerve, and anastomoses with the stylomastoid branch of the posterior auricular artery. (3) A **superior tympanic artery** runs in the canal for the Tensor tympani, and supplies this muscle and the lining membrane of the canal. (4) **Orbital branches** pass through the superior orbital fissure or through separate canals in the great wing of the sphenoid, to anastomose with the lacrimal or other branches of the ophthalmic artery. (5) **Temporal branches** pass through foramina in the great wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

Applied Anatomy.—The middle meningeal is an artery of considerable surgical importance, as it may be torn in fractures of the temporal region of the skull, or, indeed, by injuries causing separation of the dura mater from the bone, without fracture. The injury may be followed by considerable hemorrhage between the bone and dura mater, which produces symptoms of compression of the brain, and requires trephining for its relief. As the compression implicates the motor region of the cortex, paralysis on the opposite side of the body forms the prominent symptom of the lesion. The anterior branch of this artery crosses the sphenoidal angle of the parietal bone at a point 4 cm. behind the zygomatic process of the frontal bone, and 4.5 cm. above the zygomatic arch. From this point it passes upward and slightly backward to the sagittal suture, lying about 1.25 to 2 cm. behind the coronal suture. The posterior branch runs backward over the squama of the temporal bone. In order to expose the anterior branch of the artery, a point is taken 4 cm. above the zygomatic arch and the same distance behind the zygomatic process of the frontal bone. Here the pin of the trephine is to be applied. A horseshoe-shaped flap, measuring 8 cm. in length and transversely, and consisting of all the structures of the scalp down to and including the pericranium, is first made, with its base just above the zygomatic arch. This flap is reflected and a 2.5 cm. trephine applied. After the crown of bone has been removed, the blood clot is exposed, and gently got rid of, and if possible the bleeding-point must be found and controlled.

The **Accessory Meningeal Branch** (*ramus meningeus accessorius; small meningeal or parvidural branch*) is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the semilunar ganglion and dura mater.

The **Inferior Alveolar Artery** (*a. alveolaris inferior; inferior dental artery*) descends with the inferior alveolar nerve to the mandibular foramen on the medial surface of the ramus of the mandible. It runs along the mandibular canal in the substance of the bone, accompanied by the nerve, and opposite the first premolar tooth divides into two branches, incisor and mental. The **incisor branch** is continued forward beneath the incisor teeth as far as the middle line, where it anastomoses with the artery of the opposite side; the **mental branch** escapes with the nerve at the mental foramen, supplies the chin, and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a **lingual branch** which descends with the lingual nerve and supplies the mucous membrane of the mouth. As the inferior alveolar artery enters the foramen, it gives off a **mylohyoid branch** which runs in the mylohyoid groove, and ramifies on the under surface of the Mylohyoideus. The inferior alveolar artery and its incisor branch during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the roots, and supply the pulp of the teeth.

Branches of the Second or Pterygoid Portion.—

Deep Temporal.
Pterygoid.

Masseteric.
Buccinator.

The **Deep Temporal Branches**, two in number, **anterior** and **posterior**, ascend between the Temporalis and the pericranium; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and great wing of the sphenoid.

The **Pterygoid Branches** (*rami pterygoidei*), irregular in their number and origin, supply the Pterygoidei.

The **Masseteric Artery** (*a. masseterica*) is small and passes lateralward through the mandibular notch to the deep surface of the Masseter. It supplies the muscle, and anastomoses with the masseteric branches of the external maxillary and with the transverse facial artery.

The **Buccinator Artery** (*a. buccinatoria; buccal artery*) is small and runs obliquely forward, between the Pterygoideus internus and the insertion of the Temporalis, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the external maxillary and with the infraorbital.

Branches of the Third or Pterygopalatine Portion.—

Posterior Superior Alveolar.
Infraorbital.
Descending Palatine.

Artery of the Pterygoid Canal.
Pharyngeal.
Sphenopalatine.

The **Posterior Superior Alveolar Artery** (*a. alveolaris superior posterior; alveolar or posterior dental artery*) is given off from the internal maxillary, frequently in conjunction with the infraorbital just as the trunk of the vessel is passing into the pterygopalatine fossa. Descending upon the tuberosity of the maxilla, it divides into numerous branches, some of which enter the alveolar canals, to supply the molar and premolar teeth and the lining of the maxillary sinus, while others are continued forward on the alveolar process to supply the gums.

The **Infraorbital Artery** (*a. infraorbitalis*) appears, from its direction, to be the continuation of the trunk of the internal maxillary, but often *arises* in conjunction with the posterior superior alveolar. It runs along the infraorbital groove and canal with the infraorbital nerve, and emerges on the face through the infraorbital foramen, beneath the infraorbital head of the Quadratus labii superioris. While in the canal, it gives off (*a*) **orbital branches** which assist in supplying the Rectus inferior and Obliquus inferior and the lacrimal sac, and (*b*) **anterior superior alveolar**

branches which descend through the anterior alveolar canals to supply the upper incisor and canine teeth and the mucous membrane of the maxillary sinus. On the face, some branches pass upward to the medial angle of the orbit and the lacrimal sac, anastomosing with the angular branch of the external maxillary artery; others run toward the nose, anastomosing with the dorsal nasal branch of the ophthalmic; and others descend between the *Quadratus labii superioris* and the *Caninus*, and anastomose with the external maxillary, transverse facial, and buccinator arteries. The four remaining branches *arise* from that portion of the internal maxillary which is contained in the pterygopalatine fossa.

The **Descending Palatine Artery** (*a. palatina descendens*) descends through the pterygopalatine canal with the anterior palatine branch of the sphenopalatine ganglion, and, emerging from the greater palatine foramen, runs forward in a groove on the medial side of the alveolar border of the hard palate to the incisive canal; the terminal branch of the artery passes upward through this canal to anastomose with the sphenopalatine artery. Branches are distributed to the gums, the palatine glands, and the mucous membrane of the roof of the mouth; while in the pterygopalatine canal it gives off twigs which descend in the lesser palatine canals to supply the soft palate and palatine tonsil, anastomosing with the ascending palatine artery.

Applied Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as it is in danger of being wounded, and may give rise to formidable hemorrhage; it has even been found necessary to plug the pterygopalatine canal in order to arrest the bleeding.

The **Artery of the Pterygoid Canal** (*a. canalis pterygoidei*; *Vidian artery*) passes backward along the pterygoid canal with the corresponding nerve. It is distributed to the upper part of the pharynx and to the auditory tube, sending into the tympanic cavity a small branch which anastomoses with the other tympanic arteries.

The **Pharyngeal Branch** is very small; it runs backward through the pharyngeal canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and to the auditory tube.

The **Sphenopalatine Artery** (*a. sphenopalatina*; *nasopalatine artery*) passes through the sphenopalatine foramen into the cavity of the nose, at the back part of the superior meatus. Here it gives off its **posterior lateral nasal branches** which spread forward over the conchæ and meatuses, anastomose with the ethmoidal arteries and the nasal branches of the descending palatine, and assist in supplying the frontal, maxillary, ethmoidal, and sphenoidal sinuses. Crossing the under surface of the sphenoid the sphenopalatine artery ends on the nasal septum as the **posterior septal branches**; these anastomose with the ethmoidal arteries and the septal branch of the superior labial; one branch descends in a groove on the vomer to the incisive canal and anastomoses with the descending palatine artery.

THE TRIANGLES OF THE NECK (Fig. 589).

The side of the neck presents a somewhat quadrilateral outline, limited, *above*, by the lower border of the body of the mandible, and an imaginary line extending from the angle of the mandible to the mastoid process; *below*, by the upper border of the clavicle; in *front*, by the middle line of the neck; *behind*, by the anterior margin of the *Trapezius*. This space is subdivided into two large triangles by the *Sternocleidomastoideus*, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process and occipital bone above. The triangular space in front of this muscle is called the **anterior triangle**; and that behind it, the **posterior triangle**.

Anterior Triangle.—The anterior triangle is bounded, in *front*, by the middle line of the neck; *behind*, by the anterior margin of the *Sternocleidomastoideus*; its *base*, directed upward, is formed by the lower border of the body of the mandible,

and a line extending from the angle of the mandible to the mastoid process; its apex is below, at the sternum. This space is subdivided into four smaller triangles by the Digastricus above, and the superior belly of the Omohyoideus below. These smaller triangles are named the **inferior carotid**, the **superior carotid**, the **submaxillary**, and the **suprahyoid**.

FIG. 589.—The triangles of the neck.

The **Inferior Carotid**, or **Muscular Triangle**, is bounded, in *front*, by the median line of the neck from the hyoid bone to the sternum; *behind*, by the anterior margin of the Sternocleidomastoideus; *above*, by the superior belly of the Omohyoideus. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying in which are some of the branches of the supraclavicular nerves. Beneath these superficial structures are the Sternohyoideus and Sternothyroideus, which, together with the anterior margin of the Sternocleidomastoideus, conceal the lower part of the common carotid artery.¹ This vessel is enclosed within its sheath, together with the internal jugular vein and vagus nerve; the vein lies lateral to the artery on the right side of the neck, but overlaps it below on the left side; the nerve lies between the artery and vein, on a plane posterior to both. In front of the sheath are a few descending filaments from the ansa hypoglossi; behind the sheath are the inferior thyroid artery, the recurrent nerve, and the sympathetic trunk; and on its medial side, the oesophagus, the trachea, the thyroid gland, and the lower part of the larynx. By cutting into the upper part of this space, and slightly displacing the Sternocleidomastoideus, the common carotid artery may be tied below the Omohyoideus.

The **Superior Carotid**, or **Carotid Triangle**, is bounded, *behind* by the Sternocleidomastoideus; *below*, by the superior belly of the Omohyoideus; and *above*, by the Stylohyoideus and the posterior belly of the Digastricus. It is covered by the integument, superficial fascia, Platysma and deep fascia; ramifying in which are branches of the facial and cutaneous cervical nerves. Its floor is formed by parts of the Thyrohyoideus, Hyoglossus, and the Constrictores pharyngis medius and inferior. This

¹ Therefore the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sternocleidomastoideus; that is to say, they lie under that muscle, which forms the posterior border of the triangle. But as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it is expedient to study the relations of all these parts together.

space when dissected is seen to contain the upper part of the common carotid artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are somewhat concealed from view by the anterior margin of the Sternocleidomastoideus, which overlaps them. The external and internal carotids lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space: the superior thyroid, running forward and downward; the lingual, directly forward; the external maxillary, forward and upward; the occipital, backward; and the ascending pharyngeal, directly upward on the medial side of the internal carotid. The veins met with are: the internal jugular, which lies on the lateral side of the common and internal carotid arteries; and veins corresponding to the above-mentioned branches of the external carotid—viz., the superior thyroid, the lingual, common facial, ascending pharyngeal, and sometimes the occipital—all of which end in the internal jugular. The nerves in this space are the following. In front of the sheath of the common carotid is the ramus descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotids above, curving around the origin of the occipital artery. Within the sheath, between the artery and vein, and behind both, is the vagus nerve; behind the sheath, the sympathetic trunk. On the lateral side of the vessels, the accessory nerve runs for a short distance before it pierces the Sternocleidomastoideus; and on the medial side of the external carotid, just below the hyoid bone, may be seen the internal branch of the superior laryngeal nerve; and, still more inferiorly, the external branch of the same nerve. The upper portion of the larynx and lower portion of the pharynx are also found in the front part of this space.

The **Submaxillary** or **Digastric Triangle** corresponds to the region of the neck immediately beneath the body of the mandible. It is bounded, *above*, by the lower border of the body of the mandible, and a line drawn from its angle to the mastoid process; *below*, by the posterior belly of the Digastricus and the Stylohyoideus; in *front*, by the anterior belly of the Digastricus. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying in which are branches of the facial nerve and ascending filaments of the cutaneous cervical nerve. Its *floor* is formed by the Mylohyoideus, Hyoglossus, and Constrictor pharyngis superior. It is divided into an anterior and a posterior part by the stylomandibular ligament. The anterior part contains the submaxillary gland, superficial to which is the anterior facial vein, while imbedded in the gland is the external maxillary artery and its glandular branches; beneath the gland, on the surface of the Mylohyoideus, are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle contains the external carotid artery, ascending deeply in the substance of the parotid gland; this vessel lies here in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, superficial temporal, and internal maxillary branches: more deeply are the internal carotid, the internal jugular vein, and the vagus nerve, separated from the external carotid by the Styloglossus and Stylopharyngeus, and the glossopharyngeal nerve.¹

The **Suprahyoid Triangle** is limited *behind* by the anterior belly of the Digastricus, in *front* by the middle line of the neck between the mandible and the hyoid bone; *below*, by the body of the hyoid bone; its *floor* is formed by the Mylohyoideus. It contains one or two lymph glands and some small veins; the latter unite to form the anterior jugular vein.

Posterior Triangle.—The posterior triangle is bounded, in *front*, by the Sternocleidomastoideus; *behind*, by the anterior margin of the Trapezius; its *base* is formed

¹ The remark made about the inferior carotid triangle applies also to this one. The structures enumerated as contained in its posterior part lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland, all these parts are spoken of together.

by the middle third of the clavicle; its *apex*, by the occipital bone. The space is crossed, about 2.5 cm. above the clavicle, by the inferior belly of the Omohyoideus, which divides it into two triangles, an **upper or occipital**, and a **lower or subclavian**.

The **Occipital Triangle**, the larger division of the posterior triangle, is bounded, in *front*, by the Sternocleidomastoideus; *behind*, by the Trapezius; *below*, by the Omohyoideus. Its *floor* is formed from above downward by the Splenius capitis, Levator scapulae, and the Scaleni medius and posterior. It is covered by the skin, the superficial and deep fasciæ, and by the Platysma below. The accessory nerve is directed obliquely across the space from the Sternocleidomastoideus, which it pierces, to the under surface of the Trapezius; below, the supraclavicular nerves and the transverse cervical vessels and the upper part of the brachial plexus cross the space. A chain of lymph glands is also found running along the posterior border of the Sternocleidomastoideus, from the mastoid process to the root of the neck.

The **Subclavian Triangle**, the smaller division of the posterior triangle, is bounded, *above*, by the inferior belly of the Omohyoideus; *below*, by the clavicle; its *base* is formed by the posterior border of the Sternocleidomastoideus. Its *floor* is formed by the first rib with the first digitation of the Serratus anterior. The size of the subclavian triangle varies with the extent of attachment of the clavicular portions of the Sternocleidomastoideus and Trapezius, and also with the height at which the Omohyoideus crosses the neck. Its height also varies according to the position of the arm, being diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downward, when that bone is depressed. This space is covered by the integument, the superficial and deep fasciæ and the Platysma, and crossed by the supraclavicular nerves. Just above the level of the clavicle, the third portion of the subclavian artery curves lateralward and downward from the lateral margin of the Scalenus anterior, across the first rib, to the axilla, and this is the situation most commonly chosen for ligaturing the vessel. Sometimes this vessel rises as high as 4 cm. above the clavicle; occasionally, it passes in front of the Scalenus anterior, or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is not usually seen in this space; but in some cases it rises as high as the artery, and has even been seen to pass with that vessel behind the Scalenus anterior. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely behind the clavicle are the transverse scapular vessels; and traversing its upper angle in the same direction, the transverse cervical artery and vein. The external jugular vein runs vertically downward behind the posterior border of the Sternocleidomastoideus, to terminate in the subclavian vein; it receives the transverse cervical and transverse scapular veins, which form a plexus in front of the artery, and occasionally a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavius also crosses this triangle about its middle, and some lymph glands are usually found in the space.

The Internal Carotid Artery (A. Carotis Interna) (Fig. 590).

The **internal carotid artery** supplies the anterior part of the brain, the eye and its appendages, and sends branches to the forehead and nose. Its size, in the adult, is equal to that of the external carotid, though, in the child, it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. It occasionally has one or two flexures near the base of the skull, while in its passage through the carotid canal and along the side of the body of the sphenoid bone it describes a double curvature and resembles the italic letter *S*.

Course and Relations.—In considering the course and relations of this vessel it may be divided into four portions: **cervical**, **petrous**, **cavernous**, and **cerebral**.

Cervical Portion.—This portion of the internal carotid begins at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upward, in front of the transverse processes of the upper three cervical vertebræ, to the carotid canal in the petrous portion of the temporal bone. It is comparatively superficial at its commencement, where it is contained

FIG. 590.—The internal carotid and vertebral arteries. Right side.

in the carotid triangle, and lies behind and lateral to the external carotid, overlapped by the Sternocleidomastoideus, and covered by the deep fascia, Platysma, and integument: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastricus and Stylohyoideus, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Styloglossus and Stylopharyngeus, the tip of the styloid process and the stylo-

hyoid ligament, the glossopharyngeal nerve and the pharyngeal branch of the vagus. It is in relation, *behind*, with the Longus capitis, the superior cervical ganglion of the sympathetic trunk, and the superior laryngeal nerve; *laterally*, with the internal jugular vein and vagus nerve, the nerve lying on a plane posterior to the artery; *medially*, with the pharynx, superior laryngeal nerve, and ascending pharyngeal artery. At the base of the skull the glossopharyngeal, vagus, accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

Petrous Portion.—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and medialward, and again ascends as it leaves the canal to enter the cavity of the skull between the lingula and petrosal process of the sphenoid. The artery lies at first in front of the cochlea and tympanic cavity; from the latter cavity it is separated by a thin, bony lamella, which is cribriform in the young subject, and often partly absorbed in old age. Farther forward it is separated from the semilunar ganglion by a thin plate of bone, which forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. Frequently this bony plate is more or less deficient, and then the ganglion is separated from the artery by fibrous membrane. The artery is separated from the bony wall of the carotid canal by a prolongation of dura mater, and is surrounded by a number of small veins and by filaments of the carotid plexus, derived from the ascending branch of the superior cervical ganglion of the sympathetic trunk.

Cavernous Portion.—In this part of its course, the artery is situated between the layers of the dura mater forming the cavernous sinus, but covered by the lining membrane of the sinus. It at first ascends toward the posterior clinoid process, then passes forward by the side of the body of the sphenoid bone, and again curves upward on the medial side of the anterior clinoid process, and perforates the dura mater forming the roof of the sinus. This portion of the artery is surrounded by filaments of the sympathetic nerve, and on its lateral side is the abducent nerve.

Cerebral Portion.—Having perforated the dura mater on the medial side of the anterior clinoid process, the internal carotid passes between the optic and oculomotor nerves to the anterior perforated substance at the medial extremity of the lateral cerebral fissure, where it gives off its terminal or cerebral branches.

Peculiarities.—The length of the internal carotid varies according to the length of the neck, and also according to the point of bifurcation of the common carotid. It arises sometimes from the arch of the aorta; in such rare instances, this vessel has been found to be placed nearer the middle line of the neck than the external carotid, as far upward as the larynx, when the latter vessel crossed the internal carotid. The course of the artery, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was altogether absent; in one of these the common carotid passed up the neck, and gave off the usual branches of the external carotid; the cranial portion of the internal carotid was replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and foramen ovale, and joined to form a single vessel.

Applied Anatomy.—The cervical part of the internal carotid is very rarely wounded. It is, however, sometimes injured by a stab or gunshot wound in the neck, or even occasionally by a stab from within the mouth, as when a person receives a thrust from the end of a parasol, or falls down with a tobacco pipe in his mouth. Although the internal carotid lies about 2 cm. behind and lateral to the tonsil, instances have occurred in which the artery has been wounded during the operation of excision of the tonsil, and fatal hemorrhage has supervened. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sternocleidomastoideus, from the angle of the mandible to the upper border of the thyroid cartilage. The superficial structures being divided, and the Sternocleidomastoideus defined and drawn lateralward, the areolar tissue must be carefully separated and the posterior belly of the Digastricus and the hypoglossal nerve sought for as guides to the vessel. When the artery is found, the external carotid should be drawn medialward and the Digastricus upward, and the aneurism needle passed from the lateral to the medial side.

Obstruction of the internal carotid by embolism or thrombosis may give rise to symptoms of cerebral anemia and softening if the collateral circulation is ill-developed. The patient suffers from giddiness, with failure of the mental powers; and convulsions, coma, or hemiplegia on the opposite side of the body, may be observed.

Branches.—The cervical portion of the internal carotid gives off no branches. Those from the other portions are:

<i>From the Petrous Portion</i>	{ Caroticotympanic. Artery of the Pterygoid Canal.
<i>From the Cavernous Portion</i>	{ Cavernous. Hypophyseal. Semilunar. Anterior Meningeal. Ophthalmic.
<i>From the Cerebral Portion</i>	{ Anterior Cerebral. Middle Cerebral. Posterior Communicating. Choroidal.

1. The **caroticotympanic branch** (*ramus caroticotympanicus*; *tympanic branch*) is small; it enters the tympanic cavity through a minute foramen in the carotid canal, and anastomoses with the anterior tympanic branch of the internal maxillary, and with the stylomastoid artery.

2. The **artery of the pterygoid canal** (*a. canalis pterygoidei* [Vidii]; *Vidian artery*) is a small, inconstant branch which passes into the pterygoid canal and anastomoses with a branch of the internal maxillary artery.

3. The **cavernous branches** are numerous small vessels which supply the hypophysis, the semilunar ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of them anastomose with branches of the middle meningeal.

4. The **hypophyseal branches** are one or two minute vessels supplying the hypophysis.

5. The **semilunar branches** are small vessels to the semilunar ganglion.

6. The **anterior meningeal branch** (*a. meningea anterior*) is a small branch which passes over the small wing of the sphenoid to supply the dura mater of the anterior cranial fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

7. The **ophthalmic artery** (*a. ophthalmica*) (Fig. 591) arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the medial side of the anterior clinoid process, and enters the orbital cavity through the optic foramen, below and lateral to the optic nerve. It then passes over the nerve to reach the medial wall of the orbit, and thence horizontally forward, beneath the lower border of the Obliquus superior, and divides it into two terminal branches, the **frontal** and **dorsal nasal**. As the artery crosses the optic nerve it is accompanied by the nasociliary nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebrae superioris.

Branches.—The branches of the ophthalmic artery may be divided into an **orbital group**, distributed to the orbit and surrounding parts; and an **ocular group**, to the muscles and bulb of the eye.

Orbital Group.

Lacrimal.
Supraorbital.
Posterior Ethmoidal.
Anterior Ethmoidal.
Medial Palpebral.
Frontal.
Dorsal Nasal.

Ocular Group.

Central Artery of the Retina.
Short Posterior Ciliary.
Long Posterior Ciliary.
Anterior Ciliary.
Muscular.

The **Lacrimal Artery** (*a. lacrimalis*) arises close to the optic foramen, and is one of the largest branches derived from the ophthalmic: not infrequently it is given off before the artery enters the orbit. It accompanies the lacrimal nerve along the upper border of the Rectus lateralis, and supplies the lacrimal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the **lateral palpebral arteries**; they run medialward in the upper and lower lids respectively and anastomose with the medial palpebral arteries, forming an arterial circle in this situation. The lacrimal artery give off one or two **zygomatic branches**, one of which passes through the zygomatico-temporal foramen, to reach the temporal fossa, and anastomoses with the deep temporal arteries; another appears on the cheek through the zygomatico-facial foramen, and anastomoses with the transverse facial. A **recurrent branch** passes backward through the lateral part of the superior orbital fissure to the dura mater, and anastomoses with a branch of the middle meningeal artery. The lacrimal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

Dorsal nasal Medial palpebral

Anterior ethmoid

Posterior ethmoid

*Zygomatic branches
of lacrimal*

M.

FIG. 591.—The ophthalmic artery and its branches.

The **Supraorbital Artery** (*a. supraorbitalis*) springs from the ophthalmic as that vessel is crossing over the optic nerve. It passes upward on the medial borders of the Rectus superior and Levator palpebrae, and meeting the supraorbital nerve accompanies it between the periosteum and Levator palpebrae to the supraorbital foramen; passing through this it divides into a superficial and a deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the frontal branch of the superficial temporal, and the artery of the opposite side. This artery in the orbit supplies the Rectus superior and the Levator palpebrae, and sends a branch across the pulley of the Obliquus superior, to supply the parts at the medial palpebral commissure. At the supra-orbital foramen it frequently transmits a branch to the diploë.

The **Ethmoidal Arteries** are two in number: **posterior** and **anterior**. The **posterior ethmoidal artery**, the smaller, passes through the posterior ethmoidal canal, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches which descend into the nasal cavity through apertures in the cribriform plate, anastomosing with branches of the sphenopalatine. The **anterior ethmoidal artery** accompanies the nasociliary nerve through the anterior ethmoidal canal, supplies the anterior and middle ethmoidal cells and frontal sinus, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches; these latter descend into the nasal cavity through the slit by the side of the crista galli, and, running along the groove on the inner surface of the nasal bone, supply branches to the lateral wall and septum of the nose, and a terminal branch which appears on the dorsum of the nose between the nasal bone and the lateral cartilage.

The **Medial Palpebral Arteries** (*aa. palpebrales mediales; internal palpebral arteries*), two in number, **superior** and **inferior**, arise from the ophthalmic, opposite the pulley of the Obliquus superior; they leave the orbit to encircle the eyelids near their free margins, forming a superior and an inferior arch, which lie between the Orbicularis oculi and the tarsi. The **superior palpebral** anastomoses, at the lateral angle of the orbit, with the zygomaticoörbital branch of the temporal artery and with the upper of the two lateral palpebral branches from the lacrimal artery; the **inferior palpebral** anastomoses, at the lateral angle of the orbit, with the lower of the two lateral palpebral branches from the lacrimal and with the transverse facial artery, and, at the medial part of the lid, with a branch from the angular artery. From this last anastomoses a branch passes to the nasolacrimal duct, ramifying in its mucous membrane, as far as the inferior meatus of the nasal cavity.

The **Frontal Artery** (*a. frontalis*), one of the terminal branches of the ophthalmic, leaves the orbit at its medial angle with the supratrochlear nerve, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supraorbital artery, and with the artery of the opposite side.

The **Dorsal Nasal Artery** (*a. dorsalis nasi; nasal artery*), the other terminal branch of the ophthalmic, emerges from the orbit above the medial palpebral ligament, and, after giving a twig to the upper part of the lacrimal sac, divides into two branches, one of which crosses the root of the nose, and anastomoses with the angular artery, the other runs along the dorsum of the nose, supplies its outer surface; and anastomoses with the artery of the opposite side, and with the lateral nasal branch of the external maxillary.

The **Central Artery of the Retina** (*a. centralis retinae*) is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the optic nerve, but about 1.25 cm. behind the eyeball it pierces the nerve obliquely, and runs forward in the centre of its substance to the retina. Its mode of distribution will be described with the anatomy of the eye.

The **Ciliary Arteries** (*aa. ciliares*) are divisible into three groups, the long and short, posterior, and the anterior. The **short posterior ciliary arteries** from six to twelve in number, arise from the ophthalmic, or its branches; they pass forward around the optic nerve to the posterior part of the eyeball, pierce the sclera around the entrance of the nerve, and supply the choroid and ciliary processes. The **long posterior ciliary arteries**, two in number, pierce the posterior part of the sclera at some little distance from the optic nerve, and run forward, along either side of the eyeball, between the sclera and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle, the **circulus arteriosus major**, around the circumference of the iris, from which numerous converging branches run, in the substance of the iris, to its pupillary margin, where they form a second arterial circle, the **circulus arteriosus minor**. The **anterior ciliary arteries** are derived from

the muscular branches; they run to the front of the eyeball in company with the tendons of the Recti, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the cornea and end in the *circulus arteriosus major*.

The **Muscular Branches**, (*rami musculares*), two in number, **superior and inferior**, frequently spring from a common trunk. The **superior**, often wanting, supplies the Levator palpebrae superioris, Rectus superior, and Obliquus superior. The **inferior**, more constantly present, passes forward between the optic nerve and Rectus inferior, and is distributed to the Recti lateralis, medialis, and inferior, and the Obliquus inferior. This vessel gives off most of the anterior ciliary arteries. Additional muscular branches are given off from the lacrimal and supraorbital arteries, or from the trunk of the ophthalmic.

FIG. 592.—The arteries of the base of the brain. The temporal pole of the cerebrum and a portion of the cerebellar hemisphere have been removed on the right side.

8. The **anterior cerebral artery** (*a. cerebri anterior*) (Figs. 592, 593, 594) arises from the internal carotid, at the medial extremity of the lateral cerebral fissure. It passes forward and medialward across the anterior perforated substance, above the optic nerve, to the commencement of the longitudinal fissure. Here it comes into close relationship with the opposite artery, to which it is connected by a short trunk, the **anterior communicating artery**. From this point the two vessels run side by side in the longitudinal fissure, curve around the genu of the corpus callosum, and turning backward continue along the upper surface of the corpus callosum to its posterior part, where they end by anastomosing with the posterior cerebral arteries.

Branches.—In its course the anterior cerebral artery gives off the following branches:

Antero-medial Ganglionic.
Inferior.

Anterior.
Middle.

Posterior.

The **Antero-medial Ganglionic Branches** are a group of small arteries which *arise* at the commencement of the anterior cerebral artery; they pierce the anterior perforated substance and lamina terminalis, and supply the rostrum of the corpus

FIG. 593.—Outer surface of cerebral hemisphere, showing areas supplied by cerebral arteries.

callosum, the septum pellucidum, and the head of the caudate nucleus. The **inferior branches**, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and internal orbital gyrus. The **anterior branches** supply a part of the superior frontal gyrus, and send twigs over the edge of the hemisphere to the superior and middle frontal gyri and upper part of the anterior central gyrus. The **middle branches** supply the corpus callosum, the cingulate gyrus, the medial surface of the superior frontal gyrus, and the upper part of the anterior central gyrus. The **posterior branches** supply the precuneus and adjacent lateral surface of the hemisphere.

FIG. 594.—Medial surface of cerebral hemisphere, showing areas supplied by cerebral arteries.

The **Anterior Communicating Artery** (*a. communicans anterior*) connects the two anterior cerebral arteries across the commencement of the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterward divides; or it may be wholly, or partially, divided into two. Its length averages about 4 mm., but varies greatly. It gives off some of the antero-medial ganglionic vessels, but these are principally derived from the anterior cerebral.

9. The **middle cerebral artery** (*a. cerebri media*) (Figs. 592, 593), the largest branch of the internal carotid, runs at first lateralward in the lateral cerebral or

Sylvian fissure and then backward and upward on the surface of the insula, where it divides into a number of branches which are distributed to the lateral surface of the cerebral hemisphere.

Branches.—The branches of this vessel are the:

Antero-lateral Ganglionic.	Ascending Parietal.
Inferior Lateral Frontal.	Parietotemporal.
Ascending Frontal.	Temporal.

The **Antero-lateral Ganglionic Branches**, a group of small arteries which arise at the commencement of the middle cerebral artery, are arranged in two sets: one, the **internal striate**, passes upward through the inner segments of the lentiform nucleus, and supplies it, the caudate nucleus, and the internal capsule; the other, the **external striate**, ascends through the outer segment of the lentiform nucleus, and supplies the caudate nucleus and the thalamus. One artery of this group is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the **artery of cerebral hemorrhage**. It ascends between the lentiform nucleus and the external capsule, and ends in the caudate nucleus. The **inferior lateral frontal** supplies the inferior frontal gyrus (*Broca's convolution*) and the lateral part of the orbital surface of the frontal lobe. The **ascending frontal** supplies the anterior central gyrus. The **ascending parietal** is distributed to the posterior central gyrus and the lower part of the superior parietal lobule. The **parietotemporal** supplies the supra-marginal and angular gyri, and the posterior parts of the superior and middle temporal gyri. The **temporal branches**, two or three in number, are distributed to the lateral surface of the temporal lobe.

10. The **posterior communicating artery** (*a. communicans posterior*) (Fig. 592) runs backward from the internal carotid, and anastomoses with the posterior cerebral, a branch of the basilar. It varies in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other. From its posterior half are given off a number of small branches, the **postero-medial ganglionic branches**, which, with similar vessels from the posterior cerebral, pierce the posterior perforated substance and supply the medial surface of the thalami and the walls of the third ventricle.

11. The **anterior choroidal** (*a. chorioidea; choroid artery*) is a small but constant branch, which arises from the internal carotid, near the posterior communicating artery. Passing backward and lateralward between the temporal lobe and the cerebral peduncle, it enters the inferior horn of the lateral ventricle through the choroidal fissure and ends in the choroid plexus. It is distributed to the hippocampus, fimbria, tela chorioidea of the third ventricle, and choroid plexus.

THE ARTERIES OF THE BRAIN.

Since the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the pathological lesions which may occur in this part of the nervous system, it is important to consider a little more in detail the manner in which the vessels are distributed.

The cerebral arteries are derived from the internal carotid and vertebral, which at the base of the brain form a remarkable anastomosis known as the **arterial circle of Willis**. It is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind by the two posterior cerebral arteries, branches of the basilar, which are connected on either side with the internal carotid by the posterior communicating

(Figs. 592, 595). The parts of the brain included within this arterial circle are the lamina terminalis, the optic chiasma, the infundibulum, the tuber cinereum, the corpora mamillaria, and the posterior perforated substance.

The three trunks which together supply each cerebral hemisphere arise from the arterial circle of Willis. From its anterior part proceed the two anterior cerebrals, from its antero-lateral parts the middle cerebrals, and from its posterior part the posterior cerebrals. Each of these principal arteries gives origin to two different systems of secondary vessels. One of these is named the **ganglionic system**, and the vessels belonging to it supply the thalami and corpora striata; the other is the **cortical system**, and its vessels ramify in the pia mater and supply the cortex and subjacent brain substance. These two systems do not communicate at any point of their peripheral distribution, but are entirely independent of each other, and there is

between the parts supplied by the two systems a borderland of diminished nutritive activity, where, it is said, softening is especially liable to occur in the brains of old people.

The Ganglionic System.—All the vessels of this system are given off from the arterial circle of Willis, or from the vessels close to it. They form six principal groups: (I) the **antero-medial group**, derived from the anterior cerebrals and anterior communicating; (II) the **postero-medial group**, from the posterior cerebrals and posterior communicating; (III and IV) the right and left **antero-lateral groups**, from the middle cerebrals; and (V and VI) the right and left **postero-lateral groups**, from the posterior cerebrals, after they have wound around the cerebral peduncles. The vessels of this system are larger than those of the cortical system, and are what Cohnheim designated **terminal arteries**—that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branch, so that, through any one of the vessels only a limited area of the thalamus or corpus striatum can be injected, and the injection cannot be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

FIG. 595.—Diagram of the arterial circulation at the base of the brain. A.L. Antero-lateral. A.M. Antero-medial. P.L. Postero-lateral. P.M. Postero-medial ganglionic branches.

The Cortical Arterial System.—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries. They divide and ramify in the substance of the pia mater, and give off branches which penetrate the brain cortex, perpendicularly. These branches are divisible into two classes, long and short. The **long**, or **medullary arteries**, pass through the gray substance and penetrate the subjacent white substance to the depth of 3 or 4 cm., without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The **short vessels** are confined to the cortex, where they form with the long vessels a compact net-work in the middle zone of the gray substance, the outer and inner zones being sparingly supplied with blood. The vessels of the cortical arterial system are not so strictly "terminal" as those of the ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though possible, is

frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches, or its divisions, may have the effect of producing softening in a limited area of the cortex.

THE ARTERIES OF THE UPPER EXTREMITY.

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow; but different portions of it have received different names, according to the regions through which they pass. That part of the vessel which extends from its origin to the outer border of the first rib is termed the **subclavian**; beyond this point to the lower border of the axilla it is named the **axillary**; and from the lower margin of the axillary space to the bend of the elbow it is termed **brachial**; here the trunk ends by dividing into two branches the **radial** and **ulnar**.

THE SUBCLAVIAN ARTERY (A. SUBCLAVIA) (Fig. 596).

On the right side the **subclavian artery** *arises* from the innominate artery behind the right sternoclavicular articulation; on the left side it springs from the arch of the aorta. The two vessels, therefore, in the first part of their course, differ in length, direction, and relation with neighboring structures.

In order to facilitate the description, each subclavian artery is divided into three parts. The first portion extends from the origin of the vessel to the medial border of the Scalenus anterior; the second lies behind this muscle; and the third extends from the lateral margin of the muscle to the outer border of the first rib, where it becomes the axillary artery. The first portions of the two vessels require separate descriptions; the second and third parts of the two arteries are practically alike.

First Part of the Right Subclavian Artery (Figs. 583, 596).—The first part of the right subclavian artery *arises* from the innominate artery, behind the upper part of the right sternoclavicular articulation, and passes upward and lateralward to the medial margin of the Scalenus anterior. It ascends a little above the clavicle, the extent to which it does so varying in different cases.

Relations.—It is covered, *in front*, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sternocleidomastoideus, the Sternohyoideus, and Sternothyroideus, and another layer of the deep fascia. It is crossed by the internal jugular and vertebral veins, by the vagus nerve and the cardiac branches of the vagus and sympathetic, and by the subclavian loop of the sympathetic trunk which forms a ring around the vessel. The anterior jugular vein is directed lateralward in front of the artery, but is separated from it by the Sternohyoideus and Sternothyroideus. *Below and behind* the artery is the pleura, which separates it from the apex of the lung; *behind* is the sympathetic trunk, the Longus colli and the first thoracic vertebra. The right recurrent nerve winds around the lower and back part of the vessel.

First Part of the Left Subclavian Artery (Fig. 583).—The first part of the left subclavian artery *arises* from the arch of the aorta, behind the left common carotid, and at the level of the fourth thoracic vertebra; it ascends in the superior mediastinal cavity to the root of the neck and then arches lateralward to the medial border of the Scalenus anterior.

Relations.—It is in relation, *in front*, with the vagus, cardiac, and phrenic nerves, which lie parallel with it, the left common carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein, and is covered by the Sternothyroideus, Sternohyoideus, and Sternocleidomastoideus; *behind*, it is in relation with the cesophagus, thoracic duct, left recurrent nerve, inferior cervical ganglion of the sympathetic trunk, and Longus colli; higher up, however, the cesophagus and thoracic duct lie to its right side; the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. *Medial* to it are the cesophagus, trachea, thoracic duct, and left recurrent nerve; *lateral* to it, the left pleura and lung.

Second and Third Parts of the Subclavian Artery (Fig. 596).—The second portion of the subclavian artery lies behind the Scalenus anterior; it is very short, and forms the highest part of the arch described by the vessel.

FIG. 596.—Superficial dissection of the right side of the neck, showing the carotid and subclavian arteries.

Relations.—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep cervical fascia, Sternocleidomastoideus, and Scalenus anterior. On the right side of the neck the phrenic nerve is separated from the second part of the artery by the Scalenus anterior, while on the left side it crosses the first part of the artery close to the medial edge of the muscle. *Behind* the vessel are the pleura and the Scalenus medius; *above*, the brachial plexus of nerves; *below*, the pleura. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anterior.

The **third portion** of the subclavian artery runs downward and lateralward from the lateral margin of the Scalenus anterior to the outer border of the first rib, where it becomes the axillary artery. This is the most superficial portion of the vessel, and is contained in the subclavian triangle (see page 645).

Relations.—It is covered, *in front*, by the skin, the superficial fascia, the Platysma, the supraclavicular nerves, and the deep cervical fascia. The external jugular vein crosses its medial part and receives the transverse scapular, transverse cervical, and anterior jugular veins, which frequently form a plexus in front of the artery. Behind the veins, the nerve to the Subclavius descends in front of the artery. The terminal part of the artery lies behind the clavicle and the Subclavius and is crossed by the transverse scapular vessels. The subclavian vein is in front of and at a slightly lower level than the artery. *Behind*, it lies on the lowest trunk of the brachial plexus, which intervenes between it and the Scalenus medius. *Above* and to its *lateral* side are the upper trunks of the brachial plexus and the Omohyoideus. *Below*, it rests on the upper surface of the first rib.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The origin of the right subclavian from the innominate takes place, in some cases, above the sternoclavicular articulation, and occasionally, but less frequently, below that joint. The artery may arise as a separate trunk from the arch of the aorta, and in such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority, however, it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, and passes obliquely toward the right side, usually behind the trachea, cesophagus, and right carotid, sometimes between the cesophagus and trachea, to the upper border of the first rib, whence it follows its ordinary course. In very rare instances, this vessel arises from the thoracic aorta, as low down as the fourth thoracic vertebra. Occasionally, it perforates the Scalenus anterior; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus anterior. The artery may ascend as high as 4 cm. above the clavicle, or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. The posterior border of the Sternocleidomastoideus corresponds pretty closely to the lateral border of the Scalenus anterior, so that the third portion of the artery, the part most accessible for operation, lies immediately lateral to the posterior border of the Sternocleidomastoideus.

Applied Anatomy.—An *aneurism* may form on any part of the subclavian artery, except the intrathoracic portion of the left vessel, which is said never to be the seat of aneurism. The most common site is, however, the third portion, especially on the right side, on account of the greater exposure to injury and the greater amount of use of the right upper extremity. In this situation it may cause pressure on the brachial plexus, producing pain and numbness in the arm and fingers, with loss of power or paralysis of the muscles of these parts. Edema of the arm may result from pressure on the subclavian vein. The external jugular vein may become distended and varicose. The treatment is unsatisfactory, since proximal ligation cannot be undertaken with much chance of success. If constitutional treatment and direct pressure on the aneurismal sac fail, the best treatment is excision of the sac, if it be small. In aneurisms of the first portion of this artery there is edema of the head and face, with lividity, congestion of the brain, and semi-consciousness from pressure on the internal jugular vein; and spasmodic action of the Diaphragm from pressure on the phrenic nerve. The collateral circulation is so good that blocking of the subclavian artery by embolism or thrombosis often fails to give rise to any striking signs or symptoms, beyond occasional pains in the neck and shoulder and some degree of weakness and wasting in the muscles of the arm.

Compression of the subclavian artery may be required to control hemorrhage, and there is only one situation in which it can be effectually applied, viz., where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon grasping the side of the neck should press with his thumb in the angle formed by the posterior border of the Sternocleidomastoideus with the upper border of the clavicle, downward, backward, and inward against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backward, so as to compress the artery against the Scalenus medius and transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligation of the subclavian artery may be required in cases of wounds, or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligation; and the third part of the artery is that which is most favorable for an operation, on account of its being comparatively superficial, and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumor in the axilla, the artery lies at a great depth from the surface, and this materially increases the difficulty of the operation. Under these

circumstances, it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases, its arch is about 1.25 cm. above the clavicle, occasionally as high as 4 cm., and sometimes so low as to be on a level with its upper border. If the clavicle be displaced, these variations will necessarily make the operation more or less difficult, according as the vessel is less or more accessible. The vessel is also ligatured as a preliminary measure to the complete interscapulothoracic amputation of the upper extremity, in which case the transverse scapular and transverse cervical arteries may, if found, be ligatured at the same time, making the "fore-quarter" amputation an almost bloodless procedure.

The procedure in the operation of tying the third portion of the subclavian artery is as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side, and the shoulder depressed as much as possible, the integument should be pulled downward over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sternocleidomastoideus. The object in drawing the skin downward is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downward with the skin. The soft parts should now be allowed to glide up, and the cervical fascia divided upon a director, and if the interval between the Trapezius and Sternocleidomastoideus be insufficient for the performance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen toward the medial side of the wound; this and the transverse scapular and transverse cervical veins which end in it should be held aside. If the external jugular vein be at all in the way and exposed to injury, it should be tied in two places and divided. The transverse scapular artery should be avoided, and the Omohyoideus held aside if necessary. In the space beneath this muscle, careful search must be made for the vessel; a deep layer of fascia and some connective tissue having been divided carefully, the lateral margin of the Scalenus anterior muscle must be felt for, and the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurism needle may then be passed around the artery from above downward and medialward so as to avoid including any of the branches of the brachial plexus. If the clavicle be so raised by the tumor that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anterior; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery, and the alteration in position of the surrounding parts.

The second part of the subclavian artery, the portion which rises highest in the neck, has been considered favorable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anterior, upon which lies the phrenic nerve, and at the medial side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising medially to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the lateral half or two-thirds of the Scalenus anterior, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as ligature of the third portion, until the Scalenus anterior is exposed, when it is to be divided on a director (never to a greater extent than its lateral two-thirds), and it immediately retracts. The operation is therefore merely an extension of the operation for ligature of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery which encroach upon the lateral portion of the Scalenus anterior to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side, this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome.¹ On the right side, the operation is practicable, and has been performed on several occasions. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the supine position, with the neck extended, an incision should be made along the upper border of the medial part of the clavicle, and a second along the medial border of the Sternocleidomastoideus, meeting the former at an angle. The attachments of both heads of the Sternocleidomastoideus must be divided on a director, and turned lateralward; a few small arteries and veins, and occasionally the anterior jugular, must be avoided, or, if necessary, ligatured in two places and divided, and the Sternohyoideus and Sternothyroideus divided in the same manner as the preceding muscle. After tearing through the deep fascia, the

¹ The operation has, however, been performed by J. K. Rodgers, by Halsted, and by Schumpert.

internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside, and the artery secured by passing the needle from below upward, by which the pleura is more effectually avoided. The exact position of the vagus, recurrent, and phrenic nerves and the sympathetic trunk should be borne in mind, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course, when it arises from the left side of the aortic arch, and passes in such cases behind the œsophagus, or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery, the collateral circulation is established mainly by three sets of vessels, thus described in a dissection:

1. A posterior set, consisting of the transverse scapular and the descending ramus of the transverse cervical branches of the subclavian, anastomosing with the subscapular from the axillary.

2. A medial set, produced by the connection of the internal mammary on the one hand, with the highest intercostal and lateral thoracic arteries, and the branches from the subscapular on the other.

3. A middle or axillary set, consisting of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminating either in the main trunk, or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of newly formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

The chief agent in the restoration of the axillary artery below the tumor was the subscapular artery, which communicated most freely with the internal mammary, transverse scapular and descending ramus of the transverse cervical branches of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size.¹

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by: (1) the anastomosis between the superior and inferior thyroids; (2) the anastomosis of the two vertebrals; (3) the anastomosis of the internal mammary with the inferior epigastric and the aortic intercostals; (4) the costocervical anastomosing with the aortic intercostals; (5) the profunda cervicis anastomosing with the descending branch of the occipital; (6) the scapular branches of the thyrocervical trunk anastomosing with the branches of the axillary, and (7) the thoracic branches of the axillary anastomosing with the aortic intercostals.

Branches.—The branches of the subclavian artery are:

Vertebral.

Internal mammary.

Thyrocervical.

Costocervical.

On the left side all four branches generally *arise* from the first portion of the vessel; but on the right side (Fig. 596) the costocervical trunk usually springs from the second portion of the vessel. On both sides of the neck, the first three branches arise close together at the medial border of the *Scalenus anterior*; in the majority of cases, a free interval of from 1.25 to 2.5 cm. exists between the commencement of the artery and the origin of the nearest branch.

1. The **vertebral artery** (*a. vertebralis*) (Fig. 590), is the first branch of the subclavian, and *arises* from the upper and back part of the first portion of the vessel. It is surrounded by a plexus of nerve fibres derived from the inferior cervical ganglion of the sympathetic trunk, and ascends through the foramina in the transverse processes of the upper six cervical vertebræ;² it then winds behind the superior articular process of the atlas and, entering the skull through the foramen magnum, unites, at the lower border of the pons, with the vessel of the opposite side to form the basilar artery.

Relations.—The vertebral artery may be divided into four parts: The **first part** runs upward and backward between the *Longus colli* and the *Scalenus anterior*. In front of it are the internal jugular and vertebral veins, and it is crossed by the inferior thyroid artery; the left vertebral is crossed by the thoracic duct also. Behind it are the transverse process of the seventh cervical vertebra, the sympathetic trunk and its inferior cervical ganglion. The **second part** runs upward through the foramina in the transverse processes of the upper six cervical vertebræ, and is surrounded by branches from the inferior cervical sympathetic ganglion and by a plexus of veins

¹ Guy's Hospital Reports, vol. i, 1836. Case of axillary aneurism, in which Aston Key had tied the subclavian artery on the lateral edge of the *Scalenus anterior*, twelve years previously.

² The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra, and has been seen entering that of the seventh vertebra.

which unite to form the vertebral vein at the lower part of the neck. It is situated in front of the trunks of the cervical nerves, and pursues an almost vertical course as far as the transverse process of the atlas, above which it runs upward and lateralward to the foramen in the transverse process of the atlas. The **third part** issues from the latter foramen on the medial side of the Rectus capitis lateralis, and curves backward behind the superior articular process of the atlas, the anterior ramus of the first cervical nerve being on its medial side; it then lies in the groove on the upper surface of the posterior arch of the atlas, and enters the vertebral canal by passing beneath the posterior atlantoöccipital membrane. This part of the artery is covered by the Semispinalis capitis and is contained in the **suboccipital triangle**—a triangular space bounded by the Rectus capitis posterior major, the Obliquus superior, and the Obliquus inferior. The first cervical or suboccipital nerve lies between the artery and the posterior arch of the atlas. The **fourth part** pierces the dura mater and inclines medialward to the front of the medulla oblongata; it is placed between the hypoglossal nerve and the anterior root of the first cervical nerve and beneath the first digitation of the ligamentum denticulatum. At the lower border of the pons it unites with the vessel of the opposite side to form the basilar artery.

Branches.—The branches of the vertebral artery may be divided into two sets: those given off in the neck, and those within the cranium.

Cervical Branches.

Spinal.
Muscular.

Cranial Branches.

Meningeal.
Posterior Spinal.
Anterior Spinal.
Posterior Inferior Cerebellar.
Medullary.

Spinal Branches (*rami spinales*) enter the vertebral canal through the intervertebral foramina, and each divides into two branches. Of these, one passes along the roots of the nerves to supply the medulla spinalis and its membranes, anastomosing with the other arteries of the medulla spinalis; the other divides into an ascending and a descending branch, which unite with similar branches from the arteries above and below, so that two lateral anastomotic chains are formed on the posterior surfaces of the bodies of the vertebræ, near the attachment of the pedicles. From these anastomotic chains branches are supplied to the periosteum and the bodies of the vertebræ, and others form communications with similar branches from the opposite side; from these communications small twigs arise which join similar branches above and below, to form a central anastomotic chain on the posterior surface of the bodies of the vertebræ.

Muscular Branches are given off to the deep muscles of the neck, where the vertebral artery curves around the articular process of the atlas. They anastomose with the occipital, and with the ascending and deep cervical arteries.

The **Meningeal Branch** (*ramus meningeus; posterior meningeal branch*) springs from the vertebral opposite the foramen magnum, ramifies between the bone and dura mater in the cerebellar fossa, and supplies the falx cerebelli. It is frequently represented by one or two small branches.

The **Posterior Spinal Artery** (*a. spinalis posterior; dorsal spinal artery*) arises from the vertebral, at the side of the medulla oblongata; passing backward, it descends on this structure, lying in front of the posterior roots of the spinal nerves, and is reinforced by a succession of small branches, which enter the vertebral canal through the intervertebral foramina; by means of these it is continued to the lower part of the medulla spinalis, and to the cauda equina. Branches from the posterior spinal arteries form a free anastomosis around the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessels of the opposite side. Close to its origin each gives off an ascending branch, which ends at the side of the fourth ventricle.

The **Anterior Spinal Artery** (*a. spinalis anterior; ventral spinal artery*) is a small branch, which arises near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow of the opposite side at the

level of the foramen magnum. One of these vessels is usually larger than the other, but occasionally they are about equal in size. The single trunk, thus formed, descends on the front of the medulla spinalis, and is reinforced by a succession of small branches which enter the vertebral canal through the intervertebral foramina; these branches are derived from the vertebral and the ascending cervical of the inferior thyroid in the neck; from the intercostals in the thorax; and from the lumbar, iliolumbar, and lateral sacral arteries in the abdomen and pelvis. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extend as far as the lower part of the medulla spinalis, and is continued as a slender twig on the filum terminale. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane, and the substance of the medulla spinalis, and sends off branches at its lower part to be distributed to the cauda equina.

Applied Anatomy.—Bleeding into the membranes or into the substance of the medulla spinalis itself is not common, but may occur from injuries received at birth when labor is unduly prolonged or instruments are used. It is also met with in chronic insanity, and in tetanus or strychnine poisoning.

The **Posterior Inferior Cerebellar Artery** (*a. cerebelli inferior posterior*) (Fig. 592), the largest branch of the vertebral, winds backward around the upper part of the medulla oblongata, passing between the origins of the vagus and accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches. The **medial branch** is continued backward to the notch between the two hemispheres of the cerebellum; while the **lateral** supplies the under surface of the cerebellum, as far as its lateral border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

The **Medullary Arteries** (*bulbar arteries*) are several minute vessels which spring from the vertebral and its branches and are distributed to the medulla oblongata.

The **Basilar Artery** (*a. basilaris*) (Fig. 592), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries: it extends from the lower to the upper border of the pons, lying in its median groove, under cover of the arachnoid. It ends by dividing into the two posterior cerebral arteries.

Its **branches**, on either side, are the following:

Pontine.	Anterior Inferior Cerebellar.
Internal Auditory.	Superior Cerebellar.
	Posterior Cerebral.

The **pontine branches** (*rami ad pontem; transverse branches*) are a number of small vessels which come off at right angles from either side of the basilar artery and supply the pons and adjacent parts of the brain.

The **internal auditory artery** (*a. auditiva interna; auditory artery*), a long slender branch, *arises* from near the middle of the artery; it accompanies the acoustic nerve through the internal acoustic meatus, and is distributed to the internal ear.

The **anterior inferior cerebellar artery** (*a. cerebelli inferior anterior*) passes backward to be distributed to the anterior part of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The **superior cerebellar artery** (*a. cerebelli superior*) *arises* near the termination of the basilar. It passes lateralward, immediately below the oculomotor nerve, which separates it from the posterior cerebral artery, winds around the cerebral peduncle, close to the trochlear nerve, and, arriving at the upper surface of the cerebellum, divides into branches which ramify in the pia mater and anastomose with those of the inferior cerebellar arteries. Several branches are given to the

pineal body, the anterior medullary velum, and the tela chorioidea of the third ventricle.

The **posterior cerebral artery** (*a. cerebri posterior*) (Figs. 592, 593, 594) is larger than the preceding, from which it is separated near its origin by the oculomotor nerve. Passing lateralward, parallel to the superior cerebellar artery, and receiving the posterior communicating from the internal carotid, it winds around the cerebral peduncle, and reaches the tentorial surface of the occipital lobe of the cerebrum, where it breaks up into branches for the supply of the temporal and occipital lobes.

The **branches** of the posterior cerebral artery are divided into two sets, **ganglionic** and **cortical**:

Ganglionic	{	Posterior-medial.	Cortical	{	Anterior Temporal.
		Posterior Choroidal.			Posterior Temporal.
		Postero-lateral.			Calcarine.
					Parietoöccipital.

Ganglionic.—The **postero-medial ganglionic branches** (Fig. 595) are a group of small arteries which *arise* at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated substance, and supply the medial surfaces of the thalami and the walls of the third ventricle. The **posterior choroidal branches** run forward beneath the splenium of the corpus callosum, and supply the tela chorioidea of the third ventricle and the choroid plexus. The **postero-lateral ganglionic branches** are small arteries which *arise* from the posterior cerebral artery after it has turned around the cerebral peduncle; they supply a considerable portion of the thalamus.

Cortical.—The cortical branches are: the **anterior temporal**, distributed to the uncus and the anterior part of the fusiform gyrus; the **posterior temporal**, to the fusiform and the inferior temporal gyri; the **calcarine**, to the cuneus and gyrus lingualis and the back part of the convex surface of the occipital lobe; and the **parietoöccipital**, to the cuneus and the precuneus.

2. The **thyrocervical trunk** (*truncus thyrocervicalis*; *thyroid axis*) (Fig. 596) is a short thick trunk, which *arises* from the front of the first portion of the subclavian artery, close to the medial border of the Scalenus anterior, and divides almost immediately into three branches, the **inferior thyroid**, **transverse scapular**, and **transverse cervical**.

The **Inferior Thyroid Artery** (*a. thyreoidea inferior*) passes upward, in front of the vertebral artery and Longus colli; then turns medialward behind the carotid sheath and its contents, and also behind the sympathetic trunk, the middle cervical ganglion resting upon the vessel. Reaching the lower border of the thyroid gland it divides into two branches, which supply the postero-inferior parts of the gland, and anastomose with the superior thyroid, and with the corresponding artery of the opposite side. The recurrent nerve passes upward generally behind, but occasionally in front, of the artery.

The **branches** of the inferior thyroid are:

Inferior Laryngeal..	Esophageal.
Tracheal.	Ascending Cervical.
	Muscular.

The **inferior laryngeal artery** (*a. laryngea inferior*) ascends upon the trachea to the back part of the larynx under cover of the Constrictor pharyngis inferior, in company with the recurrent nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the branch from the opposite side, and with the superior laryngeal branch of the superior thyroid artery.

The **tracheal branches** (*rami tracheales*) are distributed upon the trachea, and anastomose below with the bronchial arteries.

The **oesophageal branches** (*rami oesophagei*) supply the oesophagus, and anastomose with the oesophageal branches of the aorta.

The **ascending cervical artery** (*a. cervicalis ascendens*) is a small branch which *arises* from the inferior thyroid as that vessel is passing behind the carotid sheath; it runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anterior and Longus capitis. To the muscles of the neck it gives twigs which anastomose with branches of the vertebral, and it sends one or two spinal branches into the vertebral canal through the intervertebral foramina to be distributed to the medulla spinalis and its membranes, and to the bodies of the vertebræ, in the same manner as the spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries.

The **muscular branches** supply the depressors of the hyoid bone, and the Longus colli, Scalenus anterior, and Constrictor pharyngis inferior.

The **Transverse Scapular Artery** (*a. transversa scapulae; suprascapular artery*) passes at first downward and lateralward across the Scalenus anterior and phrenic

nerve, being covered by the Sternocleidomastoideus; it then crosses the subclavian artery and the brachial plexus, and runs behind and parallel with the clavicle and Subclavius, and beneath the inferior belly of the Omohyoideus, to the superior border of the scapula; it passes over the superior transverse ligament of the scapula which separates it from the suprascapular nerve, and enters the supraspinatous fossa (Fig. 597). In this situation it lies close to the bone, and ramifies between it and the Supraspinatus, to which it supplies branches. It then descends behind the neck of the scapula, through the great scapular notch and under cover of the inferior transverse ligament, to

reach the infraspinatous fossa, where it anastomoses with the scapular circumflex and the descending branch of the transverse cervical. Besides distributing branches to the Sternocleidomastoideus, Subclavius, and neighboring muscles, it gives off a **suprasternal branch**, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and an **acromial branch**, which pierces the Trapezius and supplies the skin over the acromion, anastomosing with the thoracoacromial artery. As the artery passes over the superior transverse ligament of the scapula, it sends a branch into the subscapular fossa, where it ramifies beneath the Subscapularis, and anastomoses with the subscapular artery and with the descending branch of the transverse cervical. It also sends articular branches to the acromioclavicular and shoulder-joints, and a nutrient artery to the clavicle.

FIG. 597.—The scapular and circumflex arteries.

The **Transverse Cervical Artery** (*a. transversa colli; transversalis colli artery*) lies at a higher level than the transverse scapular; it passes transversely above the inferior belly of the Omohyoideus to the anterior margin of the Trapezius, beneath which it divides into an **ascending** and a **descending branch**. It crosses in front of

the phrenic nerve and the Scaleni, and in front of or between the divisions of the brachial plexus, and is covered by the Platysma and Sternocleidomastoideus, and crossed by the Omohyoideus and Trapezius.

The **ascending branch** (*ramus ascendens; superficial cervical artery*) ascends beneath the anterior margin of the Trapezius, distributing branches to it, and to the neighboring muscles and lymph glands in the neck, and anastomosing with the superficial branch of the descending ramus of the occipital artery.

The **descending branch** (*ramus descendens; posterior scapular artery*) (Fig. 597) passes beneath the Levator scapulae to the medial angle of the scapula, and then descends under the Rhomboidei along the vertebral border of that bone as far as the inferior angle. It supplies the Rhomboidei, Latissimus dorsi and Trapezius, and anastomoses with the transverse scapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The ascending branch of the transverse cervical frequently arises directly from the thyrocervical trunk; and the descending branch from the third, more rarely from the second, part of the subclavian.

3. The **internal mammary artery** (*a. mammaria interna*) (Fig. 598) arises from the under surface of the first portion of the subclavian, opposite the thyrocervical trunk. It descends behind the cartilages of the upper six ribs at a distance of about 1.25 cm. from the margin of the sternum, and at the level of the sixth intercostal space divides into the **musculophrenic** and **superior epigastric arteries**.

Relations.—It is directed at first downward, forward, and medialward behind the sternal end of the clavicle, the subclavian and internal jugular veins, and the first costal cartilage, and passes forward close to the lateral side of the innominate vein. As it enters the thorax the phrenic nerve crosses from its lateral to its medial side. Below the first costal cartilage it descends almost vertically to its point of bifurcation. It is covered in front by the cartilages of the upper six ribs and the intervening Intercostales interni and anterior intercostal membranes, and is crossed by the terminal portions of the upper six intercostal nerves. It rests on the pleura, as far as the third costal cartilage; below this level, upon the Transversus thoracis. It is accompanied by a pair of veins; these unite above to form a single vessel, which runs medial to the artery and ends in the corresponding innominate vein.

Branches.—The branches of the internal mammary are:

Pericardiophrenic.	Intercostal.
Anterior Mediastinal.	Perforating.
Pericardial.	Musculophrenic.
Sternal.	Superior Epigastric.

The **Pericardiophrenic Artery** (*a. pericardiophrenica; a. comes nervi phrenici*) is a long slender branch, which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragma, to which it is distributed; it anastomoses with the musculophrenic and inferior phrenic arteries.

The **Anterior Mediastinal Arteries** (*aa. mediastinales anteriores; mediastinal arteries*) are small vessels, distributed to the areolar tissue and lymph glands in the anterior mediastinal cavity, and to the remains of the thymus.

The **Pericardial Branches** supply the upper part of the anterior surface of the pericardium; the lower part receives branches from the musculophrenic artery.

The **Sternal Branches** (*rami sternales*) are distributed to the Transversus thoracis, and to the posterior surface of the sternum.

The anterior mediastinal, pericardial, and sternal branches, together with some twigs from the pericardiophrenic, anastomose with branches from the intercostal and bronchial arteries, and form a **subpleural mediastinal plexus**.

The **Intercostal Branches** (*rami intercostales; anterior intercostal arteries*) supply the upper five or six intercostal spaces. Two in number in each space, these small vessels pass lateralward, one lying near the lower margin of the rib above, and the

other near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the

Intercostales interni, and then between the Intercostales interni and externi. They supply the Intercostales and, by branches which perforate the Intercostales externi, the Pectorales and the mamma.

The **Perforating Branches** (*rami perforantes*) correspond to the five or six intercostal spaces. They pass forward through the intercostal spaces, and, curving lateralward, supply the Pectoralis major and the integument. Those which correspond to the second, third, and fourth spaces give branches to the mamma, and during lactation are of large size.

The **Musculophrenic Artery** (*a. musculophrenica*) is directed obliquely downward and lateralward, behind the cartilages of the false ribs; it perforates the Diaphragma at the eighth or ninth costal cartilage, and ends, considerably reduced in size, opposite the last intercostal space. It gives off intercostal branches to the seventh, eighth, and ninth intercostal spaces; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the intercostals from the internal mammary. The musculophrenic also gives branches to the lower part of the pericardium, and others which run backward to the Diaphragma, and downward to the abdominal muscles.
